INVESTIGATING THE CELL-SPECIFIC MECHANISMS THAT DRIVE SEX  
DIFFERENCES DURING NEUROPATHIC PAIN DEVELOPMENT

by

THOMAS ALEXANDER SZABO-PARDI, BS

DISSERTATION

Presented to the Faculty of  
The University of Texas at Dallas  
in Partial Fulfillment  
of the Requirements  
for the Degree of

DOCTOR OF PHILOSOPHY IN  
COGNITION AND NEUROSCIENCE

THE UNIVERSITY OF TEXAS AT DALLAS

August 2022

## ACKNOWLEDGMENTS

I want to give a heartfelt thank you to everyone in my life that helped push me to achieve my goals. I am incredibly thankful for my friends, family and all the wonderful people I have met along my journey who have been nothing but supportive over the years. You all have instilled confidence in me whenever my resolve had wavered and have been paramount to my success as a rising scientist. I want to thank my committee, and all the faculty in the Cognition and Neuroscience program here at UTD. You all have created an environment that breeds success and have made me feel supported every step of the way. I also want to thank all past and present members of the Neuroimmunology and Behavior lab. The phrase, “it takes a village...” could not be truer in this instance. I would have never been able to learn and achieve as much as I did during my graduate studies without the help of my fellow lab mates, mentors, friends, and family. You all have made this difficult yet rewarding challenge into a memory I will cherish for the rest of my life. Lastly, I would like to thank my mentor, Dr. Michael Burton, for believing in my potential as a scientist. Without your guidance and unwavering support none of this would have been possible. Your undying passion for science is truly inspirational, and I hope to follow in your footsteps and make a lasting impact on other’s lives just as you did mine.

INVESTIGATING THE CELL-SPECIFIC MECHANISMS THAT DRIVE SEX  
DIFFERENCES DURING NEUROPATHIC PAIN DEVELOPMENT

Thomas Alexander Szabo-Pardi, PhD  
The University of Texas at Dallas, 2022

Supervising Professor: Michael Burton

Chronic pain patients often suffer from a decline in quality of life due to a lack of efficacious long-term therapeutics. Moreover, the prevalence of chronic pain conditions is on the rise, with an average increase of nearly 10 percent in patients per decade. This, coupled with the devastating impact of the opioid crisis, highlights the need for novel pain therapeutics. An extensive literature has placed microglia, the resident immune cells of the central nervous system, at the forefront of male-specific mechanisms that mediate chronic pain plasticity. Recently, efforts have been made to design studies aimed at dissecting female specific mechanisms in pain plasticity. Evidence suggests that immune-related components of nociceptors are heavily dysregulated following insult and are more directly responsible for changes in female-specific sensitization. Despite advances in the field of pain neurobiology, there remains a clear disconnect between the cellular mechanisms that underlie maladaptive chronic pain in males and females. Moreover, a lack of studies directed towards interventions during early neuropathic pain development make it difficult to assess how functional changes in cellular phenotypes following injury can be manipulated to prevent maladaptive pain plasticity from taking place. The goal of our research was to use an innovative

approach to identify nociceptor and immune cell-specific mechanisms in both the peripheral and central nervous systems that mediate sex differences during neuropathic pain development. Our findings suggest that the initial phase of neuropathic development is sexually dimorphic, characterized by nociceptor-specific signaling mechanisms in females and immune cell mediated sensitization in males which may be modulated by genetic and pharmacological manipulation of toll-like receptor 4 signaling.

# CHAPTER 1

## INTRODUCTION

### **Prevalence of Pain**

Pain is a multi-faceted, subjective experience that involves the integration of sensory systems and higher order processing centers in the brain. Pain is recognized as a biological benefit that induces defensive behaviors following injury which helps to facilitate the healing process. Dysregulation of the nervous and immune systems can often lead to maladaptive plasticity which translates to long lasting, or idiopathic pain. Chronic pain is characterized by pain that persists beyond a biological benefit and is clinically defined when symptoms are present for more than 3 months. Chronic pain is a pervasive disease that affects 10% of the world's population, with a prevalence of closer to 20-25% in some countries (Goldberg & McGee, 2011). In the United States, the Centers for Disease Control and Prevention (CDC) lists chronic pain as the number one cause of long-term disability and loss of productivity (Dahlhamer et al., 2018). For example, neuropathic pain, a major chronic pain sub-type, results from disease or trauma to the central and peripheral nervous systems and can occur in up to 30% of patients following routine operation (Kehlet, 2006). People who suffer from chronic pain often report significantly reduced quality of life which is often comorbid with other diseases (Hadi et al., 2019). Moreover, the estimated socioeconomic burden associated with chronic pain in the United States alone is between \$530 and \$635 billion per year, which is comprised of days of work missed, lost wages and direct medical costs (Smith & Hillner, 2019). The issue only becomes more complex given the lack of effective, long-term pain therapeutics.

## **Efficacy of Current Chronic Pain Pharmacotherapies**

Despite widespread research efforts, treatments for chronic pain remain largely ineffective. Acetaminophen (paracetamol) is a staple medication in the arsenal of clinicians used to manage patients pain symptoms. While it's one of the oldest analgesics used in the clinic, there is still debate centered around the specific mechanism of action. It is posited that acetaminophen's analgesic effects are derived from a combination of direct and indirect inhibition of central cyclooxygenase 1 & 2, and modulation of the endocannabinoid system (Graham et al., 2013). While these drugs have a proven record of providing positive pain management to patients suffering from acute pain, particularly when administered perioperatively, their use is often accompanied by potentially life-threatening side effects such as hepatotoxicity, in a dose-dependent manner (Scarpignato et al., 2015). These effects may be mitigated by limiting use; however, patients often require daily dosages of pain medication to effectively manage their symptoms.

COX2-selective and nonselective nonsteroidal anti-inflammatory drugs (NSAIDs) are a group of medicines used to treat acute pain and inflammation but have shown little to no benefit when used to treat chronic pain (Finnerup, 2019). While their efficacy regarding managing acute pain symptoms is undisputed, NSAID use is often accompanied by a myriad of off-target effects which can be life-threatening. For example, NSAID use may lead to increased risk of gastrointestinal hemorrhage when used perioperatively (Hadjicharalambous et al., 2016). Additionally, NSAID use carries significant cardiovascular risk, particularly when used in a chronic setting (Wang et al., 2022). Furthermore, these off-target effects prove to be highly problematic given the target populations for these medications often have cardiovascular comorbidities. These side effects

impose a significant burden on the quality of life of chronic pain patients. Even in cases where desired levels of analgesia are achieved, the multitude of off-target effects may cause unintended functional disabilities or even death.

Interestingly, some of the most widely prescribed chronic pain drugs are anticonvulsants and antidepressants, specifically gabapentin and duloxetine. Anticonvulsants typically mediate analgesia through inhibition of the alpha-2-delta subunit of voltage-gated calcium channels in the central nervous system which reduces excitatory neurotransmission (Sills & Rogawski, 2020). Antidepressants such as duloxetine have FDA approval for the treatment of chronic and acute pain and work by inhibiting reuptake of serotonin and norepinephrine during synaptic transmission (Wright et al., 2010). While gabapentin has been shown to possess efficacy when used as a pain therapeutic for conditions such as diabetic neuropathy and neuralgia, its use is often accompanied by cognitive impairments such as depression, sedation and confusion which significantly diminish quality of life (Mellegers et al., 2001). Use of gabapentin as an analgesic during surgery-induced neuropathy may also worsen cognitive impairment comorbidities (Shiers et al., 2018). Moreover, it was initially thought that gabapentin does not have addictive properties, but recent evidence suggests there is potential for misuse or abuse (Chiappini & Schifano, 2016).

Opioid-based therapies are often used to manage chronic pain and are typically effective in the short-term; however, their continued use is associated with devastating consequences. Over the last 20 years, more than 700,000 people have died from drug overdose, with 68% of those deaths linked to prescription opioid misuse (Gaskin & Richard, 2012). Moreover, long-term opioid usage

induces hyperalgesia, which leads to a cycle of heightened pain responses necessitating increased dosages (Finnerup, 2015). The eventual dependence on and tolerance of opioids from long-term usage is a sad reality for many patients suffering from chronic pain. Also, there is a marked lack of long-term, rigorous scientific studies aimed towards discovering the best clinical practice when it comes to opioid prescription. A recent review examined over 60 clinical trials, many of which were non-randomized open trials, which provided moderate evidence of long-term efficacy and low incidence of tolerance, however; this cannot serve as a substitute for randomized clinical trials (Furlan et al., 2011). Additionally, the overwhelming majority of these trials lasted for less than a month; too short to determine the lasting effects of opioid use in chronic pain management. Studies like this bring to light the complexity of the issues surrounding chronic pain management, especially when considering the enormous variability in a patient's biological and affective responses to opioid administration.

### **Sex Differences in the Clinic**

Until a 2015 mandate that outlined the necessity to include biological sex as a variable in NIH-funded research, the majority of pain research had only been in males. Recent literature has highlighted major sexual dimorphisms that alter the way researchers and clinicians alike must approach pain treatments. Consequently, the sexually dimorphic mechanisms that regulate plastic changes in cells involved in neuropathic pain development are not well understood.

Epidemiological studies have found that the prevalence of chronic pain in women is far greater than in men. Women are more likely to develop conditions that may lead to nociception or pain,

especially diseases that affect the musculoskeletal system such as fibromyalgia, osteoarthritis, and low back pain (Ruau et al., 2012). In general, female patients are also more likely to seek medical attention, 20% more likely to report experience of pain symptoms and have even been found to be more sensitive to painful stimuli than men (Steingrimsdóttir et al., 2017). Moreover, women tend to experience greater levels of cancer pain than men (Chou et al., 2018). In the clinic, women typically have worse outcomes regarding therapeutic intervention than men (Templeton, 2020). For example, women are more likely to develop chronic knee pain following total knee arthroplasty (TKA) (Vina et al., 2020). Women also report greater levels of idiopathic pain following TKA and are less responsive to pain therapeutics such as low efficacy opioids. These drugs are often less effective in women and may even function as receptor antagonists as opposed to agonists in males, highlighting fundamental sex differences in opioid system functionality (Barrett, 2006).

The influence of hormones has always been a potential culprit; however, recent evidence suggests that transient shifts in sex hormones like estrogen during the phasic nature of the estrus cycle may not be directly responsible. In fact, the dichotomy in sex-based nociception may be hardwired at birth and modulated to some degree by hormones during adulthood. A recent clinical study discovered that widespread cortical responses in pre- and full-term infants to nociceptive stimulation are different between sexes. Interestingly, no differences were found in response to innocuous touch, indicating that the signaling pathways between the sensory and nociceptive systems are not mutually exclusive (Verriotis et al., 2018). However, many preclinical studies have shown that estrogens play a significant role in pain management. For example, ovariectomized

female rodents can manifest mechanical and thermal hyperalgesia and are often more sensitive to noxious stimuli while supplementation with estrogen may reverse these effects (Chen et al., 2012; Zhang et al., 2020). Moreover, evidence suggests that the estrus cycle may modulate the biological response to pharmacological stimulation. Specifically, administration of the neurotransmitter, 5-HT, can induce more robust pain behaviors during proestrus and estrus and may be reversed by an appropriate antagonist (Kaur et al., 2018). Nonetheless, the mechanisms by which estrogen modulates nociception remain largely unknown and are an underrepresented area of pain research considering the number of conflicting findings.

### **Discovery of Toll-Like Receptors**

Toll, which is a *D. melanogaster* type-1 transmembrane protein, was initially ascribed to regulate dorsal-ventral polarity during development (Anderson et al., 1985). It was later found to facilitate antifungal response elements that protected the host against fungal infection (Lemaitre et al., 1996). The *D. melanogaster* toll protein is similar to the interleukin-1 receptor (IL-1R) which mediates inflammation through a variety of intracellular signaling processes, one of them being activation and nuclear localization of the pro-inflammatory transcription factor nuclear factor-kappa B (NF- $\kappa$ B) (Gay & Keith, 1991; Ghosh et al., 1990). Shortly after this discovery, a human homologue of the Toll protein was identified on chromosome 4p14 which indicated that a human “toll-like” protein could be responsible for initiating the innate immune response to foreign pathogens (Taguchi et al., 1996). Moreover, the human toll protein was found to also activate NF- $\kappa$ B and upregulate expression of proinflammatory cytokines such as Il-1, IL-6, and tumor necrosis factor- $\alpha$  (TNF-  $\alpha$ ) (Medzhitov et al., 1997).

The TLR family consists of a multitude of both extra (TLR1, 2, 4, 5 and 6) and intracellular (TLR3, 7, 8 and 9) receptor subtypes with a molecular weight ranging from 84-121 kD and are evolutionarily conserved (Bauer et al., 2012; Werling & Jungi, 2003). They are known as pattern-recognition receptors (PRRs) with an extracellular leucine-rich repeat (LRR) domain which is involved in both endogenous and exogenous ligand recognition, ranging from foreign pathogenic components like lipopolysaccharide (LPS) to nucleic acids such as viral RNA and CpG DNA (Uematsu & Akira, 2008). Interestingly, TLRs also contain an intracellular toll/interleukin-1 (IL-1) receptor-like (TIR) domain which is a highly conserved motif that facilitates signal transduction through a variety of protein kinases (Akira & Takeda, 2004).

It was not until the turn of the 21<sup>st</sup> century that the specific role of TLR4 in LPS detection and signal transduction was discovered (Du et al., 1999; Hoshino et al., 1999). Structurally, TLR4 forms a multi-receptor complex on the surface of a cell's extracellular membrane or endosomal compartments within the cell. It is coupled with several other proteins and adaptors such as cluster of differentiation 14 (CD14) and myeloid differentiation factor-2 (MD-2) (Kawasaki & Kawai, 2014). CD14 is a glycosylphosphatidylinositol (GPI)-anchored receptor which is known to be a co-receptor to TLR4 and is required for LPS-induced TLR4 activation (Zanoni et al., 2011). Since CD14 does not contain an intracellular tail, it cannot facilitate intracellular signaling without forming a receptor complex with TLR4/MD-2, or other toll-like receptors (Ulevitch & Tobias, 1995). LPS is a relatively large glycolipid comprised of 3 primary structural domains: lipid A tail, the core oligosaccharide, and the O antigen (Raetz et al., 2006). The lipid A tail typically forms the hydrophobic portion of the molecule and consists of an acetylated  $\beta$ -1'-6-linked glucosamine

disaccharide that forms the outer leaflet of the membrane (Raetz et al., 2006). The fundamental function of LPS in gram-negative bacteria is to serve as the structural foundation of the outer cell membrane and to establish a permeability barrier preventing entry of toxic molecules (Carpenter et al., 2016). It was discovered that mutations in the murine TLR4 gene of a hypo responsive strain (C3H/HeJ) led to a reduction in sickness behaviors in response to administration of LPS (Poltorak et al., 1998). This provided robust evidence to suggest that TLR4 is responsible for mediating the pro-inflammatory phenotype caused by LPS. Being a PRR, it was postulated that TLR4 could recognize and respond to a multitude of ligands which may mediate other cellular processes beyond just the innate immune response. Moreover, TLR4 has been shown to be expressed on a host of cells in both the central nervous system (CNS) and periphery. These include microglia (Olson & Miller, 2004), astrocytes (Bowman et al., 2003), neurons (Tang et al., 2007), macrophages (Kawai et al., 1999), dendritic cells (Ketloy et al., 2008), endothelial cells (Lu et al., 2012), fibroblasts (Bhattacharyya et al., 2018) and many more. Since TLR4 is expressed on a variety of cells with specific biological functions, considerations must be made on a per cell basis when interpreting the effects of TLR4 signaling in disease pathology. To begin to dissect the sex- and cell-specific role of TLR4 signaling in pain development our lab utilized two novel transgenic models that enable reactivation of a TLR4 allele using a cell-specific locus to drive expression of cre recombinase. Here we are able to reactivate TLR4 expression in a whole-body null background in either Nav1.8 expressing nociceptors or LysozymeM expressing peripheral macrophages. Initial characterization of these lines revealed significant sex differences in response to intraplantar administration of LPS. We find that both male and female mice lacking whole-body TLR4 do not develop mechanical hypersensitivity in response to intraplantar LPS injection (Figure 1.1A-F;

Table 1.1). Interestingly, reactivation of TLR4 on peripheral macrophages only recapitulates a wild type behavioral phenotype in male, but not females (Figure 1.1A-C; Table 1.1). This suggests that the TLR4-dependent signaling mechanisms activated by LPS between male and female macrophages differs. Moreover, reactivation of TLR4 on Nav1.8 nociceptors only recapitulates a wild type phenotype in females (Figure 1.1D-F; Table 1.1). We believe that direct activation of nociceptors by TLR4 ligands in females initiates inflammatory pathways necessary for the development of inflammatory pain. This initial endeavor has laid the foundation for future studies present in this dissertation.

**Figure 1.1. Sex- and cell-specific effects of TLR4 activation by LPS in DRG nociceptors and peripheral macrophages.** Hind paw mechanical thresholds were measured prior to intraplantar injection of LPS and on timepoints: 1hr, 4hr, 8 hr and 24hrs post-injection. **A)** Representative von Frey plot of Male TLR4<sup>TB/TB</sup> (n=6), LysM:TLR4<sup>TB/TB</sup> (n=5) and WT (n=5) mice injected with intraplantar LPS. **B)** Representative von Frey plot of female TLR4<sup>TB/TB</sup> (n=6), LysM:TLR4<sup>TB/TB</sup> (n=6) and WT (n=5) mice injected with intraplantar LPS. **C)** Representative plot of mechanical hypersensitivity effect sizes with sexes combined. **D)** Representative von Frey plot of Male

TLR4<sup>TB/TB</sup> (n=6), Nav1.8:TLR4<sup>TB/TB</sup> (n=7) and WT (n=) mice injected with intraplantar LPS. **E**) Representative von Frey plot of female TLR4<sup>TB/TB</sup> (n=6), Nav1.8:TLR4<sup>TB/TB</sup> (n=7) and WT (n=7) mice injected with intraplantar LPS. **F**) Representative plot of mechanical hypersensitivity effect sizes with sexes combined. Statistical comparisons are described in Table 1.1. Data were analyzed using a 2way ANOVA.

Beyond the recognition of LPS, TLR4 is also capable of binding a multitude of pathogenic components such as teichuronic acid from gram-positive bacteria and the *Dengue virus* NS1 protein (Modhiran et al., 2015; Yang et al., 2001). The extracellular domain of TLR4 exhibits a significant amount of sequence divergence due to the polymorphic nature of the LRR (Thomas et

al., 2006; Werling et al., 2009). This is typically comprised of the first 82 amino acids within the proximal region of the extracellular domain, and is involved in recognition and response to TLR4 ligands (Alvarez et al., 2006). The intra and inter-species variation in response to LPS, and other ligands, is attributed to the poor conservation of this extracellular amino acid sequence. In addition to the previously discussed exogenous pathogen-associated molecular patterns (PAMPs), TLR4 also recognizes endogenous danger-associated molecular patterns (DAMPs) such as heat shock proteins (HSPs), high mobility group box 1 (HMGB1) and fibronectin (Chase et al., 2007; Gondokaryono et al., 2007; Yu et al., 2006). Moreover, TLR4 has been shown to recognize long-chain saturated fatty acids. The principal component of LPS that carries its immunostimulatory activity is the lipid A moiety which contains numerous saturated fatty acyl chains required for interaction with the TLR4/MD-2 receptor complex (Steimle et al., 2016). Evidence suggest inhibition of microglial TLR4 by neutralizing antibodies prevents initiation of a pro-inflammatory phenotype following palmitic acid or fatty acid exposure which is typically found in the western diet (Nicholas et al., 2017; Shi et al., 2006). This indicates that TLR4 plays a critical role in the innate immune system's ability to recognize and respond to foreign pathogens and facilitate host defense, but it is also crucial for the detection of endogenous signals related to tissue injury, sterile inflammation, and obesity-induced inflammation.

### **TLR4 Signaling: MyD88- and TRIF-Dependent Pathways**

TLR4 signaling pathways can generally be classified into two categories: MyD88- and TRIF-dependent pathways. These two pathways are responsible for activation of various intracellular signaling cascades based on specific adaptor protein recruitment. Upon activation of the

TLR4/MD-2 heterodimer and internalization, MyD88 forms a complex with a family of IRAK kinases. Following formation of this complex, IRAK4 activates IRAK1 which becomes phosphorylated and is subsequently released from MyD88 (Jiang et al., 2002; Kollwe et al., 2004). IRAK1 then associates with the RING-domain E3 ubiquitin ligase TRAF6. The ubiquitin-conjugating enzymes, UBC13 and UEV1A, along with TRAF6 promote the K63-linked polyubiquitin chains generated by TRAF6 which facilitates activation of TAK1 (Ajibade et al., 2013; Chen, 2012). Activation of TAK1 leads to association with the IKK complex, allowing for activation of the NF- $\kappa$ B and MAPK pathways. The IKK complex is comprised of a regulatory subunit, IKK $\gamma$ , and two catalytic subunits: IKK $\alpha$  and IKK $\beta$ . TAK1 interacts with the IKK complex through ubiquitin chains which enable the phosphorylation of serine residues on IKK $\beta$  and facilitates its activation (Kawai & Akira, 2010). The IKK complex phosphorylates I $\kappa$ B $\alpha$ , which constitutively prevents NF- $\kappa$ B nuclear translocation. NF- $\kappa$ B is a dimeric transcription factor that is part of the Rel-homology domain-containing protein family. This includes RelB, c-Rel, p50/NF- $\kappa$ B1, p52/NF- $\kappa$ B2, and p65/RelA. The prototypical version of NF- $\kappa$ B is a heterodimer comprised of the p50 and p65 subunits (Hayden & Ghosh, 2004). Phosphorylation of I $\kappa$ B $\alpha$  facilitates proteasome degradation by 26S, which allows NF- $\kappa$ B to translocate to the nucleus of the cell and bind to  $\kappa$ B sites that initiate inflammatory gene transcription such as TNF $\alpha$ , IL-1, IL-6 and IL-12 (Ferreiro & Komives, 2010). TAK1 activation can also lead to intracellular signaling through MAPKs such as JNK, ERK1, ERK2, and p38 which facilitate activation of AP-1 transcription factors that regulate inflammatory processes (Gunnell et al., 2010). Interestingly, TAK1 deficiency has been shown to reduce or even inhibit inflammatory cytokine production in mouse embryonic fibroblasts (Lluis et al., 2010). However, deficiency of TAK1 in mouse neutrophils does not

recapitulate this reduction in inflammatory signaling, suggesting that TLR4 may have cell-specific differences in signaling capabilities (Ajibade et al., 2012).

During endosomal TLR4 signaling, the TIR domain uses TRAM to recruit TRIF. Interaction between TRIF and TRAF6 leads to the recruitment of kinase RIP-1 which activates the TAK1 complex by facilitating association between TAB1-3 and TAK1, similar to the MyD88-dependent pathway (Kagan et al., 2008). This, in turn, leads to activation of the previously discussed NF- $\kappa$ B and AP-1 pathways and the induction of inflammatory cytokines. Conversely, interaction between TRIF and TRAF3 facilitates recruitment of IKK-related kinases such as TBK1 and IKKi. These are directly responsible for IRF3 phosphorylation (Fitzgerald et al., 2003). Like NF- $\kappa$ B, IRF3 forms a dimer upon activation and translocates to the nucleus of the cell where it induces expression of type-1 interferons (Kolb et al., 2014).

### **Modulation of Pain by TLR4**

Over the last decade evidence has been mounting which suggests TLR4 that is a critical mediator of the nervous and immune systems inflammatory response during pain (DeLeo et al., 2004; Guo & Schluesener, 2007; Heiman et al., 2014). During peripheral inflammation, TLR4 and CD14 gene expression is increased in the spinal cord of rats injected with intraplantar complete Freund's adjuvant (CFA) (Raghavendra et al., 2004). These results were confirmed nearly a decade later where another group had shown an increase in microglia reactivity following intraplantar CFA injection by measuring upregulation of OX-42 and TLR4 expression in the dorsal spinal cord (Zhao et al., 2015). Moreover, intraplantar or intraoral injection of LPS induces robust mechanical

and thermal hypersensitivity which is accompanied by upregulation of various inflammatory cytokines. The observed phenotypes are blocked by modulation of TLR4 activity or MyD88 deficiency (Araya et al., 2020; Calil et al., 2014). Taken together, these suggest that both central and peripherally expressed TLR4 mediates acute inflammatory pain.

In addition to inflammatory pain, TLR4 has also been shown to be involved in chemotherapy-induced peripheral neuropathy (CIPN). Paclitaxel, a taxol-based chemotherapeutic, engages similar inflammatory intracellular signaling pathways as the classical TLR4 ligand, LPS (Zaks-Zilberman et al., 2001). This is evident by paclitaxel utilizing the same MD-2 accessory protein required for LPS signal transduction and upregulating inflammatory cytokines such as IL-1, TNF $\alpha$  and IL-6 in the blood (O'Brien et al., 1995; Resman et al., 2008). More recently, paclitaxel has been shown to interact with TLR4 in the DRG and spinal cord. Paclitaxel treatment upregulates TLR4 expression in these tissues and facilitates canonical activation of MyD88-mediated signaling pathways which results in a behavioral pain phenotype (Li et al., 2014). Blockade of TLR4 signaling using LPS-RS seemingly reverses the pain phenotype, which further implicates the direct activation of TLR4 by chemotherapeutics in peripheral CIPN development (Illias et al., 2022). While evidence suggests that these effects may be neuronally mediated by subpopulations of IB4 and CGRP expressing nociceptors, paclitaxel has also been shown to modulate pro-inflammatory, or M1, polarization of peripheral macrophages in a TLR4-dependent manner (Wanderley et al., 2018). As M1-polarized macrophages produce a multitude of neuromodulatory cytokines, it's likely that the effects of chemotherapeutics on TLR4 activation in immune cells also contributes CIPN development.

TLR4 has also been shown to play a significant role in opioid-induced hyperalgesia. While this seems paradoxical, evidence suggests that mu opioids can lead to increased pain sensitivity (Weber et al., 2017). It is believed that certain opioids can bind to TLR4 using the MD-2 adaptor, similar to LPS, which facilitates inflammatory signaling (J. Li et al., 2016). By acting as TLR4 ligands, traditional opioid receptor agonists may induce a pain phenotype, or enhance sensitivity through hyperalgesic priming (Ellis et al., 2016). These effects can be reversed or blocked by inhibiting activation of TLR4 using pharmacological antagonists such as TAK-242 or LPS-RS (Grace et al., 2016).

### **Neuroimmune Modulation of Chronic Pain**

Within the last decade there have been numerous studies aimed towards dissecting sex differences in chronic pain development. While the scientific community has made significant progress towards addressing nearly a century of male-biased pain research, there are still many questions left unanswered and mechanisms that remain unclear. Given the disproportionate number of women impacted by chronic pain and the lack of effective therapeutics, understanding the sex- and cell-specific differences in neuroimmune modulation of pain is necessary to appropriately design and execute research targeted at therapeutic development (Bartley & Fillingim, 2013).

It is now widely appreciated that the nervous and immune systems communicate with one another to coordinate their dynamic responses to stimulation. Immune cells can modulate the activity of pain-sensing neurons, nociceptors, by releasing pro- or anti-inflammatory cytokines. In turn, nociceptors communicate with immune cells by releasing immunomodulatory neuropeptides, chemokines, cytokines, and microRNAs (Talbot et al., 2016). Emerging evidence suggests that the

interaction between the nervous and immune systems is bidirectional, indicating that crosstalk between these systems is necessary to not only maintain homeostasis, but also respond appropriately to tissue injury and infection (Pinho-Ribeiro et al., 2017). To understand how these systems interact with one another, we must first discuss how they individually sense danger signals.

Within the dorsal root ganglia (DRG) there exists a heterogenous population of nociceptive neurons that are characterized by their varying degrees of myelination, size and signaling capabilities (Alshawaf et al., 2018). Recent single-cell RNA-sequencing (scRNA-seq) data indicates that there are 10 major populations of nociceptive neurons in the murine DRG, with numerous subtypes that further distinguish their unique physiological properties (C. L. Li et al., 2016). These nociceptors actively respond to external stimuli such as changes in temperature, mechanical or chemical thresholds. At baseline, these cells play a necessary role in alerting the individual to potentially harmful situations and inducing defensive behaviors. However, dysregulation of peripheral nociceptive circuitry may lead to maladaptive plasticity and chronic pain. The mechanism by which chronic pain occurs in the periphery is likely due to ectopic activity of peripheral nerves, or the DRG, which is generated as a result of Na<sup>+</sup> channel upregulation and hypersensitization to neuromodulators (Black et al., 2008). Transient receptor potential channels (TRP channels), specifically TRPA1 and TRPV1, are crucial components of nociceptor signaling as they regulate pain and temperature sensation through Ca<sup>2+</sup> influx (Song & Yuan, 2010). These TRP channels have been implicated in the pathogenesis of both acute and chronic pain making them a prime candidate for pain therapeutics (Duitama et al., 2020). Nociceptors also express a

host of PRRs like TLRs, Nod-like receptors (NLRs), C-type lectin receptors (CLRs) and cytosolic DNA sensory (CDSs) that are responsible for mediating changes in nociceptor sensitivity during tissue injury or infection (Ackland et al., 2013). Out of these PRRs, TLR4, specifically, has been shown to possess the highest expression levels in DRG neurons (Zheng et al., 2019). Interestingly, evidence suggests that in the DRG and trigeminal ganglia (TG) TLR4 and TRPV1 are functionally coupled, meaning that TLR4 can directly modulate activity of TRPV1. Infusion of LPS in dissociated TG and DRG neurons potentiated capsaicin-induced responses such as rapid  $\text{Ca}^{2+}$  influx and calcitonin gene-related peptide (CGRP) release, both of which are not directly linked to TLR4 signaling cascades (Diogenes et al., 2011; Wu et al., 2019). In TLR4 knockout mice, capsaicin-induced pain is significantly reduced, which is intriguing given that capsaicin is known to signal exclusively through TRPV1. Moreover, these findings suggest that the TIR adaptor molecule, a specific component of TRIF-dependent TLR4 intracellular signaling, is responsible for preventing activation-induced endocytosis of TRPV1 (Min et al., 2018). Taken together, these studies reveal a unique interaction between TLR4 and TRPV1 which enhance the context by which we understand nociceptor physiology. While TLR4 does not contain any electrically-coupled signaling mechanisms, it possesses the ability to modulate  $\text{Nav}$  channel activity—an essential component of nociceptive transmission. Phosphorylated-p65 (p-p65), an active subunit of NF- $\kappa$ B, can reversibly interact with  $\text{Nav}1.7$  sodium channels in DRG nociceptors within minutes of phosphorylation. This interaction increases  $\text{Nav}1.7$  currents by slowing inactivation and facilitating recovery following depolarization (Xie et al., 2019). While the direct mechanisms involved are yet to be elucidated, this work demonstrates regulation of voltage-dependent nociceptor activity in a

transcription-independent manner. These data highlight the ability of TLR4 to modulate nociceptor signaling in numerous ways.

While the basic mechanisms of neuroimmune modulation of chronic pain are well appreciated, not all is equal between sexes. For example, microglia in the CNS were thought to possess a more male-specific role in mediating the development of chronic pain (Inyang, 2019; Sorge, 2011; Sorge, 2015). Conversely, a study that compared central and peripheral immune cell transcriptional profiles following spinal-nerve ligation (SNL) found that peripheral immune cells were considerably more dysregulated following injury and highlighted sex-specific differences in the adaptive immune response (Lopes, 2017). RNA-seq analysis of both male and female DRG neurons following peripheral chronic constriction injury (CCI) revealed sex-specific differences in gene expression. For example, colony-stimulating factor 1 (CSF1) is expressed de-novo following nerve injury in the DRG and is transported to the spinal cord where it acts on dorsal horn microglia (Guan et al., 2016). In this study, CSF1 was shown to be expressed at much higher quantities in females than males suggesting that regulation of CSF1 signaling during neuropathic injury may be a sex-dependent mechanism (Stephens et al., 2019). Intrathecal administration of CSF1 has been shown to induce a robust pro-inflammatory phenotype in male microglia characterized by amoeboid morphology and an inflammatory transcript profile. While microglia are neuromodulatory in nature, they also respond to signals sent from other immune cells. Foxp3-expressing regulatory T cells (Tregs) have been shown to suppress inflammatory activation of microglia and limit pain hypersensitivity (Wan, 2010). Results from this study indicate that CSF1 can mediate crosstalk between lymphocytes and spinal cord microglia in females by acting as a

modulator of Treg immunosuppressive activity (Kuhn et al., 2021). As peripheral macrophages also express the receptor for CSF1 (CSF1R), a follow-up study was conducted to delineate the sex-specific role of microglia vs. macrophages in CSF1-mediated neuropathic. Interestingly, it was found that deletion of CSF1 in sensory neurons only reduced tissue-resident macrophage (Ki67<sup>+</sup>) expansion in the DRG of males, but not females following spared-nerve injury (SNI). It was also demonstrated that macrophages in the DRG of both sexes contribute to the initiation and maintenance of neuropathic pain, although, it seemed to be a more male-biased mechanism (Yu et al., 2020). Taken together, these data suggest that other sensory neuron derived mechanisms differentiate male and female neuropathic pain development.

### **Sex Differences in TLR4-Mediated Neuropathic Pain Development**

Over the last decade TLR4 has made its way into the spotlight of pain research. Although, its exact sex- and cell-specific role in mediating chronic pain development and maintenance have been controversial. One of the first studies to implicate TLR4 signaling in neuropathic pain development sought to characterize the functional role of microglia TLR4 in response to spinal nerve ligation (SNL). They found that TLR4 whole body null mice not only attenuated the inflammatory response of spinal microglia, but also reduced the nociceptive behavioral phenotype seen after nerve injury (Tanga et al., 2005). Subsequent studies have corroborated these findings by pharmacologically inhibiting spinal TLR4 activation with LPS-RS, naloxone, naltrexone, and FP-1—all of which function as TLR4 antagonists with varying degrees of specificity and efficacy (Bettoni et al., 2008; Hutchinson et al., 2008). Lastly, chemotherapy-induced neuropathic pain is one of the major dose-limiting side effects of cancer treatments. TLR4 has been shown to recognize various taxol-based

chemotherapeutics and engage inflammatory intracellular signaling mechanisms similar to LPS and HMGB1 (Szajnik et al., 2009). It was found that activation of TLR4 expressed by CGRP and isolectin B4 (IB4) positive nociceptive neurons in the DRG induced acute sensitization of TRPV1-mediated  $\text{Ca}^{2+}$  responses (Li, Adamek, et al., 2015; Li et al., 2014). Moreover, early nociceptive behaviors were correlated with increased activity of the MyD88-dependent pathway and activity of the TRIF-dependent pathway was elevated during later time points. This suggests that signal transduction by TLR4 is dynamic in nature and differences in the specific pathways activated may be responsible for the initiation vs. maintenance of neuropathic pain. While these studies do provide convincing evidence that suggests immune-mediated TLR4 signaling contributes to neuropathic pain development, biological sex was not considered as a variable. It was not until a few years later that the sex-specific contribution of TLR4 in both inflammatory and neuropathic pain was addressed. It was found that intrathecal administration of LPS induced a robust pain phenotype in male, but not female mice and antagonism of spinal TLR4 reversed this effect in only males. Moreover, SNI induced neuropathic pain behaviors in both male and female mice, but only male mice showed transient attenuation of pain behaviors following intrathecal LPS-RS injection (Sorge, 2011). Some data suggest that the role of TLR4 in inflammatory and neuropathic pain development is reliant on the timing of TLR4 modulation. Intrathecal LPS facilitated mechanical hypersensitivity development in both male and female mice; however, inhibition of spinal TLR4 signaling by TAK-242 prevented development of allodynia but could not reverse established allodynia in males (Woller et al., 2016). These results were confirmed using TLR4 whole body knockout mice. While these results seem contradictory, they may be explained by differences in the strain of mouse used and serotype and dose of LPS. In accordance with the previously

discussed study, another group had demonstrated a sex-specific role of TLR4 in SNL-induced neuropathic pain. Their data suggests that TLR4 whole body null females do not exhibit a reduction in mechanical hypersensitivity like their male counterparts (Stokes et al., 2013). Interestingly, they also show that MyD88-deficient mice have a reduction in activated transcription factor 3 (ATF3) expression in DRG neurons. This was one of the first studies to suggest that TLR4 either directly, or indirectly influences expression of neuronal injury markers in the periphery. However, these findings are not always recapitulated in subsequent studies.

To date, almost all studies had been focused on central effects of TLR4 signaling. To address this, a research group had generated a unique transgenic model to assess the role of both central microglia and peripheral macrophages and TLR4 signaling in chronic pain. Interestingly, their results suggest that microglia equally participate in the imitation of neuropathic mechanical hypersensitivity in both males and females, but different cell types mediate its maintenance. Moreover, they show that ablation of microglia prior to injury only delays the onset of neuropathic pain, but synergistic ablation of both microglia and macrophages prevents neuropathic pain development (Peng, 2016). To address discrepancies in the temporal and cell-specific role TLR4 in neuropathic pain, a recent study used a conditional knockout mouse line which enabled deletion of TLR4 from microglia, specifically. They found that systemic antagonism of TLR4 is effective at improving chronic pain outcomes in both sexes when administered at the time of injury as opposed to when pain is already established. Their data shows that late conditional knockout of TLR4 only results in partial improvement in allodynia of both sexes, suggesting that microglia TLR4 plays less of a role in the maintenance of neuropathic pain (Huck et al., 2021).

An important consideration is the model and inflammatory mediators used to study the effects of TLR4 in chronic pain. HMGB1, also known as amphoterin, is a highly dynamic nuclear chromatin-binding protein that orchestrates key biological events such as sterile inflammation and chemoattraction based on its redox biology (Kwak et al., 2020). HMGB1 is capable of signaling through multiple receptors, including TLR2, TLR4 and the receptor for glycation and end products (RAGE) (Hori et al., 1995; Park et al., 2004). HMGB1 may be released from the nuclear envelope of cells in two primary ways: active release and passive secretion. Active release of HMGB1 is reliant on hyperacetylation of two nuclear localization sequence (NLS) sites which allows it to accumulate in the cytoplasm (Youn & Shin, 2006). Passive secretion of HMGB1 results from cell death, including apoptosis, autophagy, and necrosis (Qin et al., 2006; Quarato et al., 2016; Thorburn et al., 2009). Intracellular HMGB1 exists in its all thiol form (at-HMGB1) and can be oxidized to the disulfide form (ds-HMGB1) when reactive oxygen species (ROS) present in the extracellular matrix facilitate disulfide bridge formation between cysteine residues 23 and 45 (Venereau et al., 2013). Ds-HMGB1 functions as an inflammatory cytokine that induces preferential activation of TLR4 (Yamasoba et al., 2016). HMGB1 has been shown to be upregulated in both sensory neurons in the DRG, as well as peripheral immune cells and glia in response to neuropathic injury. Upregulation of HMGB1 was also associated with a transition from nuclear to cytosolic localization which is indicative of active release (Müller et al., 2004). Inhibition of HMGB1 signaling by a neutralizing antibody prevented mechanical allodynia development and cytosolic localization of the protein, suggesting that peripheral HMGB1 signaling plays a significant role in the development of neuropathic pain (Shibasaki et al., 2010). Interestingly, this study was focused entirely on the effects of HMGB1 signaling through RAGE,

and not TLR4. Moreover, only male rats were used in these experiments. Another study demonstrates that administration of dsHMGB1 was shown to increase excitability of dissociated DRG neurons. Treatment with an HMGB1 inhibitor, glycyrrhizin (GL), was able to reverse the HMGB1-dependent increase in neuronal excitability. Moreover, systemic inhibition of HMGB1 signaling was able to reverse mechanical allodynia resulting from tibial nerve injury (TNI) which is a model of neuropathic pain (Feldman et al., 2012). Distinct from the previously discussed study, these effects were interpreted more so in the context of TLR4-dependent signaling and were done in female rats. A more recent study highlights the effects of central HMGB1-TLR4 signaling on collagen antibody -induced arthritic (CAIA) pain. They also demonstrate that intrathecal administration of dsHMGB1 induces pain-like behaviors in mice of both sexes, and it TLR4-dependent. Moreover, pharmacological inhibition of spinal HMGB1 signaling reverses CAIA pain (Agalave et al., 2014). This study provides additional evidence to support the role of HMGB1 in inflammatory and neuropathic pain, but it was also one of the first to directly assess sex-differences in HMGB1-TLR4 signaling. Although these findings do not seem to recapitulate the Sorge et al., 2011 study that found robust sex differences in spinal TLR4 signaling, it does seem suggest that there may be mechanistic differences in the specific ligands, signaling pathways, and cell types responsible for neuropathic pain development between males and females. The involvement of sex- and cell-specific HGMB1 signaling in the periphery has not been extensively reported on until recently.

Our initial investigations were aimed at studying the underlying mechanisms that may attribute to the protective effect of upstream TLR4 inhibition. As an initial endeavor, we utilized two

transgenic models that allow for conditional deletion of TLR4 from a cell-specific locus: Nav1.8 (Jia et al., 2021) on peripheral nociceptors or LysozymeM (Jia et al., 2014) on peripheral macrophages. As previously discussed, evidence suggests that HMGB1 is heavily involved in mediating inflammation through TLR4 signaling. Since TLR4 is expressed on neuron and immune cells, we sought to dissect the sex- and cell-specific effects of intraplanar HMGB1 administration on mechanical hypersensitivity. We discovered that TLR4 on macrophages were necessary in males (Fig. 1.2A & C; Table 1.2) and TLR4 on nociceptors were necessary in females to induce a painful behavior phenotype (Fig. 1.2B & D; Table 1.2). Additionally, we wanted to characterize the role of TLR4 in hyperalgesic priming which may reveal insights as to the mechanisms that underlie the transition from acute to chronic pain. Once the animals had returned to baseline, we performed an intraplanar injection of a subthreshold dose of prostaglandin E2 and measured mechanical hypersensitivity. Again, we found that TLR4 activation by HMGB1 on macrophages was necessary to elicit the primed phenotype in males (Fig. 1.2A & C; Table 1.2), but it was TLR4 activation by HMGB1 on nociceptors for females (Fig. 1.2B & D; Table 1.2). More recently, a study found that inhibition of TLR4 signaling in peripheral macrophages attenuated dsHMGB1-induced pain behaviors in male, but not female mice, suggesting that the cell types responsible for mediating peripheral pain mechanisms differs between sexes (Rudjito, 2020). Using conditional TLR4 knockout in DRG nociceptors, they also demonstrate that HMGB1 mediates CAIA pain through TLR4 signaling in both sexes. Another study confirmed these findings by using a similar genetic and CAIA pain model. Moreover, by conditional deletion of HMGB1 from the whole DRG neuron population, they confirm that HMGB1 is also responsible for neuropathic pain development during SNI in females. The specific receptors for HMGB1, neuronal subtypes, and

male-specific mechanisms were not addressed (Yang et al., 2021). Therefore, studies that evaluate the effectiveness of inhibiting both TLR4 and HMGB1 signaling will shed light on the sex- and cell-specific mechanisms of chronic pain.

**Figure 1.2. Sex- and cell-specific effects of TLR4 activation by HMGB1 in DRG nociceptors and peripheral macrophages.** **A)** Hind paw mechanical withdrawal thresholds were measured prior to 1  $\mu$ g HMGB1 injection and at 1hr, 3hr, 8hr, 24hr and day 14 post injection in male TLR4<sup>fl/fl</sup> vehicle (n=6), TLR4<sup>fl/fl</sup> HMGB1 (n=8), LysM-TLR4<sup>fl/fl</sup> vehicle (n=8), LysM-TLR4<sup>fl/fl</sup> HMGB1 (n=9) mice. On day 14 mice were injected with a subthreshold dose of PGE2 and mechanical withdrawal thresholds were measured at 3hr and 24hr post injection. **B)** Hind paw mechanical withdrawal thresholds were measured prior to 1  $\mu$ g HMGB1 injection and at 1hr, 3hr, 8hr, 24hr and day 14 post injection in female TLR4<sup>fl/fl</sup> vehicle (n=6), TLR4<sup>fl/fl</sup> HMGB1 (n=7), LysM-TLR4<sup>fl/fl</sup> vehicle (n=5), LysM-TLR4<sup>fl/fl</sup> HMGB1 (n=8) mice. On day 14 mice were injected with a

subthreshold dose of PGE2 and mechanical withdrawal thresholds were measured at 3hr and 24hr post injection. **C)** Hind paw mechanical withdrawal thresholds were measured prior to 1  $\mu$ g HMGB1 injection and at 1hr, 3hr, 8hr, 24hr and day 14 post injection in male TLR4<sup>fl/fl</sup> vehicle (n=7), TLR4<sup>fl/fl</sup> HMGB1 (n=6), Nav1.8-TLR4<sup>fl/fl</sup> vehicle (n=8), Nav1.8-TLR4<sup>fl/fl</sup> HMGB1 (n=8) mice. On day 14 mice were injected with a subthreshold dose of PGE2 and mechanical withdrawal thresholds were measured at 3hr and 24hr post injection. **D)** Hind paw mechanical withdrawal thresholds were measured prior to 1  $\mu$ g HMGB1 injection and at 1hr, 3hr, 8hr, 24hr and day 14 post injection in female TLR4<sup>fl/fl</sup> vehicle (n=5), TLR4<sup>fl/fl</sup> HMGB1 (n=9), Nav1.8-TLR4<sup>fl/fl</sup> vehicle (n=6), Nav1.8-TLR4<sup>fl/fl</sup> HMGB1 (n=9) mice. On day 14 mice were injected with a subthreshold dose of PGE2 and mechanical withdrawal thresholds were measured at 3hr and 24hr post injection. Data are represented as the standard error of the mean and were analyzed using a 2-way ANOVA and Tukey's *post-hoc* comparisons. Statistical comparisons are provided in Table 1.2.

**Table 1.2.** Statistical comparisons of the data represented in Figure 1.2.

**CHAPTER 2**

**THE ROLE OF MICROGLIA VERSUS PERIPHERAL MACROPHAGES IN  
MALADAPTIVE PLASTICITY AFTER NERVE INJURY**

Authors – Thomas A. Szabo-Pardi, Nilesh M. Agalave, Michael D. Burton

## **Microglia and macrophages in the development of maladaptive plastic changes after peripheral nerve injury**

Microglia and macrophages encompass the innate immune response to injury in the central and peripheral nervous systems, respectively, and are intimately involved in the pathogenesis of maladaptive changes (Tsuda, 2019). These dynamic cells can influence neuronal activity in active and quiescent states. Conflicting findings argue that peripheral macrophages facilitate the development of nerve injury-induced neuropathic pain, as opposed to central microglia (Lopes, 2017; Yu et al., 2020). It is imperative to discern their spatiotemporal contributions to the development and maintenance of maladaptive conditions, such as neuropathic pain (Inoue & Tsuda, 2018). The individual role of these cell types is difficult to parse out because both microglia and macrophages exhibit a keen ability to react quickly to injury and remain reactive after injury-induced changes. Appropriate methods to isolate and characterize these cells in downstream applications is necessary to uncover key findings (Agalave, 2020).

While the location and time points these cells mediate maladaptive changes remain unclear, it is obvious that certain neuroimmune activation pathways, such as Fractalkine (CX<sub>3</sub>CL1)-Fractalkine receptor (CX<sub>3</sub>CR1), high mobility group box 1 (HMGB1)-toll-like receptor 4 (TLR4), ATP-Purinergic channels, and HMGB1-protease activated receptor 2 (PAR2), are important in the neuroimmune signaling process. Interestingly, along with cell-type etiology of maladaptive plasticity, evidence points to an underlying sexual dimorphic mechanism in immune cell signaling

in response to injury. This sex difference can be attributed to “biased signaling” processing in similar cell types or different cell types altogether.

### **Contribution of macrophages and microglia in nerve injury-induced neuropathic pain models**

Several experimental nerve injury models are commonly used to study neuropathic pain, such as spared nerve injury, spinal nerve ligation, and chronic constriction injury (**Figure 2.1A**). In these models, markers of macrophage activation such as ED-1, MHC-II and Iba1 are increased from days to weeks in lumbar dorsal root ganglia (DRG) (Ristoiu, 2013). Additionally, microglia in the spinal cord exhibit similar activation kinetics as macrophages during the development of neuropathic pain following nerve injury (Ristoiu, 2013). However, it remains unclear what these cell types respective roles are in the onset and maintenance of neuropathic pain. Several inflammatory mediators such as chemokine (CC motif) ligand 2, interleukin (IL)-6, IL-1 $\beta$ , matrix metalloproteinases-2, and -9, and CX<sub>3</sub>CL1 are released following nerve injury and facilitate the activation of macrophages and microglia (Zhao et al., 2017). Activation of these cells upregulates factors that increase central excitatory neurotransmission, decrease inhibitory tone of interneurons, and promote nociceptor plasticity (Bennett et al., 2016). During the pathogenesis of nerve injury, macrophages in periphery, and microglia in the spinal cord, polarize to facilitate inflammation, neuroprotection, and tissue-repair. These cells polarize into an M1 (pro-inflammatory) or M2 (anti-inflammatory) phenotype. Typically, polarized macrophages are further classified into several subtypes which depend on the makeup of the inflammatory milieu (Martinez & Gordon, 2014). Despite substantive research regarding macrophage polarization in response to injury, it remains unclear how these cells, and their subtypes, are polarized during the development and resolution

of injury-induced neuropathic pain. Clarifying this dynamic response to injury will help improve our understanding of sexual dimorphisms that have been implicated in neuropathic pain. Moreover, polarization of microglia in the central nervous system is controversial (Ransohoff, 2016). It is difficult to discern a distinct phenotype in these cells as they often concurrently express markers of both pro-inflammatory and anti-inflammatory polarization following injury. Noteworthy, microglia are similarly active in males and females following nerve injury, however, blocking microglial activity through inhibitors such as TAK 242 (TLR4 inhibitor), CSFR1, BDNF-TrkB and p38 MAPK shows reversal of pain behaviors only in males (Tsuda, 2019). This suggests the central immune system exhibits a “biased” signaling pathway in the development of injury-induced neuropathic pain that is different between sexes. Thus, a need exists to explore these biased-intracellular signaling cascades in the context of maladaptive plasticity.

**Figure 2.1. A graphic depicting peripheral macrophage versus central microglia during a peripheral nerve injury and possible sex differences in biased signaling pathways.** (A) An illustration of different peripheral nerve injury experimental models of neuropathic pain. A prominent version of spared nerve injury (SNI) is the ligation and transection of the peroneal and tibial nerve, leaving the sural nerve intact to be sensitized. Chronic constriction injury utilizes 3 loose ligatures around the sciatic nerve trunk. The spinal nerve ligation model ligates the spinal nerve. (B) A depiction of how early peripheral nerve injury recruits macrophages/monocytes to the site of injury and dorsal root ganglia (DRG), which are activated and release inflammatory mediators such as growth factors, cytokines, danger associated molecular patterns (DAMPs) and matrix metalloproteins (MMPs). These mediators bind to their respective receptors expressed on the DRGs neuron to mediate nociception. (C) A depiction of what happens at central terminals depicts action at central terminals in the spinal cord where persistent activation of primary afferent neurons stimulates the release of inflammatory mediators that activate microglia in the dorsal horn of the spinal cord.

### **Acute-to-chronic effect of neuropathic pain on macrophage and microglia**

Timing and signaling (biased): Microglia in the dorsal horn of the spinal cord facilitate chronic pain development in both sexes but inhibiting certain second messenger systems has shown promise in males only (Tsuda, 2019). Surprisingly, no studies have found differences in altered genes between males and females in microglia after neuropathic injury, suggesting similar phenotypic profiles. It is important to note that although the authors did not map the estrus cycle over the course of the entire study, there are no differences in basal sensitivity throughout each phase of the cycle (Sorge, 2011). Moreover, there is evidence to suggest that levels of microgliosis are similar in the spinal cord of males in females after nerve injury and is not estrus cycle dependent (Taves et al., 2016; Tsuda, 2019). However, the timing post-injury could reveal a therapeutic window that explains the etiology of sex differences. Based on this principle, a recent study revealed an increase in macrophage infiltration within the DRG in males 8 days after spinal nerve ligation, suggesting sexual dimorphic mechanisms in the recruitment of macrophages in the early phase of nerve injury (Lopes, 2017). While these immune cells are activated in both sexes after nerve injury, intracellular signaling cascades may facilitate maladaptive plasticity differently in males and females. Recent evidence highlights sex-biased signaling in various immune pathways. In males, elevated androgens enhance peroxisome proliferator activated receptor (PPAR) expression that consequently inhibits nuclear factor- $\kappa$ B activity and interferon- $\gamma$  production. In contrast, estrogens in females induce PPAR to exhibit similar anti-inflammatory actions as PPAR $\alpha$  (Park & Choi, 2017) (**Figure 2.1B**). Activated macrophages in the DRG express proteins that help facilitate recruitment of various immune cells. This indicates alternative activation kinetics of the immune system where cell recruitment has a sexual dimorphic role in maladaptive plasticity. Thus,

activation of nociceptors may be different in male and female following nerve injury. The mechanisms involved in the development and maintenance of neuropathic pain are different, however, the spatiotemporal role of macrophages and microglia in the DRG and spinal cord are poorly documented. A need exists to examine the early recruitment/activation of macrophages and microglia in both sexes, and how these cells' phenotypes are altered over the pathogenesis of neuropathic pain.

**The importance of differentiating neuropathic *versus* post-surgery/injury (sham effects) and the importance of therapeutic window of opportunity in the early stage**

Since most studies investigate the therapeutic potential of altering immune cell signaling and activation after injury-induced neuropathy has developed, we sit at an important crossroad where we are able to answer questions as to how microglia and macrophages contribute to the onset of neuropathic pain. Moreover, the maladaptive/plastic effects of post-operative pain are often overlooked in studies focusing on neuropathic pain. It is imperative to discern the etiology of neuropathic, as opposed to post-operative pain. This presents a potential point of unbiased therapeutic intervention where we may attenuate, or even prevent the manifestation of neuropathic pain behaviors in both sexes. Macrophages in the DRG and microglia in spinal cord are activated early in response to nerve injury and remain active throughout its pathogenesis. Chronic activation of macrophages and microglia facilitate recruitment of other immune cells which leads to long lasting neuroimmune interactions. This reciprocal signaling maintains chronicity in nociceptive plasticity. Moreover, our lab has shown the direct involvement of HMGB1-TLR4 signaling in female nociceptors during neuropathic pain development (Szabo-Pardi et al., 2021). Thus,

modulating the early activation of macrophages and microglia may present a therapeutic approach to prevent neuropathic pain and avoid sexually biased signaling. However, we must first understand the respective contributions of these cells during the onset of injury to make conjecture as to how we should develop effective therapeutic approaches.

**What are some differentiating factors between peripheral *versus* central immune cells and how they could reveal therapeutic targets?**

The mechanisms of microglia polarization are not well understood. Traditional views regarding immune cell polarization are not well adapted to microglia. These cells are dynamic and present a spectrum of polarization markers making it difficult to distinguish phenotypes. This is compounded by evidence that suggests microglia are similarly active during the onset of neuropathic injury in both sexes. Previous therapeutic approaches using tetracycline antibiotics to inhibit microglia were unspecific and alleviate pain only in males. More recent endeavors utilize specific markers to identify microglia, which allows for a more direct therapeutic approach. In nerve injury models, activation of Kir2.1 resulted in proliferation and activation of microglia in both males and females. Additionally, TMEM119 has been identified as a specific marker for microglia in mice and humans. This allows for clear dissection of microglia from infiltrating peripheral monocytes and perivascular macrophages (Bennett et al., 2016). Lastly, P2RY12 has also been identified as a microglia specific marker and has been shown to be downregulated after nerve injury. Pharmacological manipulation of these proteins may help clarify the role of microglia specifically in central sensitization and maladaptive plasticity in response to nerve injury (**Figure 2.1**).

**CHAPTER 3**

**USE OF INTEGRATED OPTICAL CLEARING AND 2-PHOTON IMAGING TO  
INVESTIGATE SEX DIFFERENCES IN NEUROIMMUNE INTERACTIONS AFTER  
PERIPHERAL NERVE INJURY**

## **ABSTRACT**

Peripheral nerve injury induces a myriad of immune-derived symptoms that negatively impacts pain, depression, and overall quality of life. Neuroimmune differences underlie sexual dimorphisms in various pain states. The innate immune system is a source of these sex differences, which promotes inflammation and pro-nociception through bidirectional signaling with the nervous system. Spatiotemporal interactions between leukocytes and sensory neurons could hold the key to explain ascribed differences between sexes. To date, studies have found it difficult to display these interactions. We are poised to answer important questions regarding the recruitment of peripheral leukocytes to key tissues of the pain system, the dorsal root ganglia (DRG) and sciatic nerve after nerve injury. We optically clear whole DRGs and sciatic nerves and concomitantly use multi-photon microscopy and transgenic reporter lines, to visualize leukocyte dynamics involved in neuropathic pain development following nerve injury. We observed robust sexual dimorphisms in leukocyte recruitment to the lumbar DRGs after nerve injury. We also assessed immune cell size and morphology to understand activation states in the context of nervous tissue inflammation. The altered mechanisms by which the male and female immune systems respond to nerve injury are still topics of further research, however; the continued use of next-generation imaging with advanced whole tissue image analysis remains an important tool in understanding the reciprocal interactions between neuronal and non-neuronal cells.

## **INTRODUCTION**

Peripheral nerve injury often results in neuropathic pain, which is defined by trauma or lesions that disrupt the somatosensory systems. Injury-induced neuropathic pain is estimated to occur in over

30% of patients following routine operations (Kehlet, 2006). Patients often report higher levels of comorbidities, such as depression and sleep disorders which further contribute to increased pathological clinical outcomes and significantly reduce quality of life (McDermott et al., 2006). Although the prevalence of chronic pain continues to rise, the number and effectiveness of existing therapeutics remains limited (Finnerup, 2015). The increasing incidence of neuropathic pain has piqued interest in understanding the key immunologic processes involved. Previous studies have found a clinically observed difference in the prevalence and perception of pain in males vs. females (Filligim, 2009; Mogil, 2012). However, there is still a dearth of knowledge on the sexual dimorphisms observed in leukocyte trafficking, morphology, and neuroimmune interaction.

Macrophages, key myeloid-derived leukocytes have been shown to play a key role in facilitating maladaptive nociception following nerve injury (Zhuo, 2011). Moreover, the peripheral immune system, specifically macrophages, play a pivotal role in sensitization of sensory neurons (Lindborg, 2018). Macrophages in the dorsal root ganglia (DRG) and sciatic nerve (ScN) play a critical role in both the initiation and maintenance of neuropathic pain by enhancing sensory neuron transduction and excitability (Basbaum, 2009). We hypothesize that using intact tissue for 3D rendering and morphologic analysis; we will be able to differentiate spatial resolution of macrophage infiltration and their interactions with sensory neurons in a sex-specific fashion. Recent studies have shown that these macrophages demonstrate robust molecular crosstalk with sensory neurons (Yu, 2020). This remains an integral process of not only pain induction as a protective mechanism, but also a transition to maladaptive chronic pain in some instances (Renthal et al., 2020). Discovering the sex-dependent roles of macrophages in tissue injury is paramount as

the incidence macrophage-dependent chronic pain in females is lower than in males (Agalave, 2020; Rudjito, 2020; Wiesenfeld-Hallin, 2005). As such, identifying sex differences in macrophage biology will serve as a foundation for future studies aimed at exploiting immunological regulation in pain and will serve to create a more tailored approach to therapeutics.

Our group has recently developed a technique for intravital imaging using transgenic reporter mice and multiphoton microscopy (Szabo-Pardi, 2019). We wanted to adapt these methods to conceptualize the immune response to injury. Changes in cellular morphology has been associated with changes in functionality of cells (McWhorter, 2013). We used transgenic reporter animals, fluorescently labeled ( $\text{ROSA26}^{\text{tdTomatoLSL}}$ )  $\times$  LysozymeM:cre ( $\text{LysM}^+$ )-expressing leukocytes ( $\text{LysM}^{\text{tdT}^+}$ ). LysM is an antimicrobial enzyme (encoded by the *Lyz2* gene) that breaks down gram-positive bacterial cell walls and is predominately expressed by circulating neutrophils and tissue macrophages (Goren, 2009). Tissue macrophages have been shown to be upregulated within days after peripheral injury and are known to play a role in injury-induced sensitization of sensory neurons (Clausen, 1999; Kiguchi et al., 2018; Rittner, 2005). Prior studies have used techniques, such as flow cytometric analysis to quantify recruitment or infiltration of macrophages into peripheral nervous tissue, however, there are inherent limitations using this method (Ghasemlou, 2015; Lopes, 2017). Notably, a lack of clarity regarding pathogenesis and spatiotemporal visualization of macrophages in the extracellular space. Moreover, studies that investigate recruitment of any immune cell to peripheral nervous tissues rarely use both sexes, making it difficult to draw apt comparisons (Kwon, 2013; Schmid, 2013).

To provide a more robust understanding of interactions in nervous tissue after injury, we cleared tissue (ScaleS1) to enable visualization of tdTomato-tagged macrophages via multiphoton microscopy. Not only does this technique preserve the integrity of extracted tissues, but it also provides an accurate representation of cell dynamics in a diseased state (Gmez-Gavero, 2020). The ability to use whole, unsectioned tissue provides a clear advantage over conventional methods, which is made possible by visualizing the spatial relation of neuronal and non-neuronal immune cells in a three-dimensional (3-D) model. In this study, we find that male mice exhibit more robust infiltration of LysM<sup>tdT+</sup> macrophages after injury as compared to females. Additionally, we took advantage of advanced image analysis in concert with our experimental approach to group and classify the morphology of these macrophages. Recent literature has shown that macrophages exemplify distinct morphological changes differentiating into M1 and M2 phenotypes, pro-inflammatory or anti-inflammatory functions, respectively (McWhorter, 2013). In response to physiological changes and cytokine signaling, M2 macrophages are associated with an elongated, prolate morphology while M1 macrophages are associated with an oblate, flattened morphology (Bertani, 2017). This serves as an indispensable tool in our approach to elucidate sex differences after nerve injury and can be adapted to address the gap in understanding the intimate interactions between leukocytes and neurons in other aspects in neuroimmunology research.

## **MATERIALS AND METHODS**

### **Laboratory Animals**

All animal experiments were carried out in accordance with protocols approved by the Institutional Animal Care and Use Committee of the University of Texas at Dallas. Mice were housed (4–5 per

cage) in a temperature-controlled facility (20–25°C) and maintained on a 12-h light/dark cycle (lights on: 6 a.m./lights off: 6 p.m.). Mice had *ad-libitum* access to food and water and were 8–12-weeks-old during the experiments (male, 25–30 g; female, 20–25 g). Transgenic mice expressing NLS-Cre recombinase under control of the endogenous *Lyz2* promoter/enhancer elements (LysM) were obtained commercially from Jackson (Stock no: 004781). Characterization of these mice showed that heterozygous cre animals have no pain phenotype and normal electrophysiological properties (Clausen, 1999). Furthermore, transgenic mice expressing a loxP-flanked *STOP* cassette preventing expressing of tdTomato (red fluorescent protein) were purchased from Jackson (Stock no: 007909) and bred with LysM<sup>cre+</sup> animals in-house (LysM<sup>cre+</sup> × ROSA26<sup>LSLtdTomato</sup> = LysM<sup>tdT</sup>) and used for all behavioral and biochemical assays. All animals used were heterozygous for LysM<sup>cre</sup> and had at least one copy of tdTomato. All strains were backcrossed to maintain C57BL/6J genetic background with animals from Jackson Lab (stock no. 000664).

### **Surgical Procedures**

The spared nerve injury (SNI) model of neuropathic pain was used. Baseline values for behavioral experiments were established 24-h prior to surgery. Mice were anesthetized under isoflurane anesthesia (1.0–2.5%). The ipsilateral thigh was shaved and cleaned with betadine (Dynarex, NY, USA; cat no. 1425) and 70% ethanol (Decon Labs, PA, USA; cat no. 2701). The skin and muscle of the ipsilateral thigh were incised with a #11 scalpel (Thermo Fisher, MA, USA; cat no. 22-079-691) and the sciatic nerve along its three branches (common peroneal, tibial, and sural) were exposed. A tight ligature using a 5-0 silk suture (VWR, PA, USA; cat no. MV-682) was placed

around the proximal tibial and common peroneal branches, after which the nerves distal to the ligature were transected, taking care to not stretch or damage the sural nerve. The skin was closed using an auto clip (Fine Science Tools, CA, USA; cat no. 12022-09) and mice were returned to their home cages to recover (Decosterd, 2000). Sham surgeries were done identically to the SNI surgery; however, no portion of the sciatic nerve was ligated or transected. Following surgery, mice are subcutaneously administered a single dose of Gentamicin (5 mg/mL) (Sigma-Aldrich, CA, USA; cat no. G1272) as a prophylactic antibiotic. All mice were then returned to their home cages for recovery and monitored daily.

### **Behavioral Testing**

To measure mechanical hypersensitivity, mice were individually placed on an elevated wire grid inside acrylic behavior racks and allowed to habituate for ~2-h. Behavior racks were cleaned with a 1:3 ratio of a natural all-purpose and deodorant-free cleaner (Seventh Generation™, VT, USA; cat no. 22719BK-5) and DI water and wiped dry to eliminate odor cues between each reading, baseline, and experiment. The ipsilateral hind paw was then stimulated with von Frey filaments (Stoelting Co., IL, USA; cat no. 58011) using the up-down experimental paradigm (Chaplan, 1994). To assess cold allodynia (cold response) in our SNI model, mice were individually placed on the same elevated wire grid and behavior racks and allowed to habituate for ~2-h before testing. Approximately 100  $\mu$ L of biological grade acetone (Fisher Scientific, MA, USA; cat no. AI6P-4) was then applied to the lateral aspect of the ipsilateral hind paw using a 1 mL syringe (VWR, PA, USA; cat no. 309659) attached to a blunted 25 G needle (VWR, PA, USA; cat no. 305125). Cold response was assessed by paw licking, shaking, grooming behaviors and were measured over a 60-

s period (Yoon, 1994). Baseline values were taken 24-h prior to performing surgery. Mechanical hypersensitivity and cold allodynia were then measured on post-operative days 1, 3, and 5. Mechanical measures were always taken before cold response. All behavioral testing was done between 10 a.m. and 2:00 p.m. Experimenters were blinded to genotype, surgery, or both.

### **Optical Clearing**

Five days post-SNI, mice were deeply anesthetized using a mixture of ketamine (80 mg/kg) and xylazine (12 mg/kg), injected intraperitoneally, and were transcardially perfused with 10 mL of ice cold  $1 \times$  PBS (Thermofisher, MA, USA; cat no. BP3994) and then 10 mL of ice cold 4% paraformaldehyde (Sigma-Aldrich, CA, USA; cat no. F8775) using a 25G winged infusion set (Thermofisher, MA, USA; cat no. 14-840-37). Lumbar dorsal root ganglia (DRGs) (L4-5) and sciatic nerves (ScNs) were collected in 2 mL microcentrifuge tubes (Eppendorf, CT, USA; cat no. 022-43-104-8) and post-fixed in 1.5 mL of 4% paraformaldehyde (Sigma-Aldrich, CA, USA; cat no. F8775) (made in  $1 \times$  PBS) for 4-h. Fixed tissues were then transferred to a 2 mL microcentrifuge tube containing 1.5 mL of 20% sucrose solution (VWR, PA, USA; cat no. 0335-1KG) (made in  $1 \times$  PBS) for 48 h. Following cryoprotection, tissues were then transferred to a 5 mL microcentrifuge tube (Eppendorf, CT, USA; cat no. 0030-119-401), immersed in 1.5–4 mL of ScaleS1 solution and placed on a tissue nutator for ~10–14 days to achieve optimal tissue clarity (Hama, 2015). This was to enhance perfusion of the extracted tissues. ScaleS1 solution was aspirated and replaced every 48-h with fresh solution. The following reagents were used to prepare ScaleS1 solution: 4 M urea crystals (Thermofischer, MA, USA; cat no. 29700), 0.1% (wt/vol) Triton X-100 (Sigma-Aldrich, CA, USA; cat no. X100), and 10% (wt/wt) glycerol (Fischer

Scientific, MA, USA; cat no. BP229-1). In brief, urea crystals were dissolved in water using a stir bar Thermofisher, MA, USA; cat no. F37180). Next, the triton x-100 was added along with glycerol and was left to mix for an hour. The solution was made and allowed a minimum of 48-h to equilibrate before use and stored at room temperature.

### **Multiphoton Microscopy**

Optically cleared DRGs and ScNs were embedded in single 13 mm glass-bottomed cell culture plates (Thermofisher, MA, USA; cat no. 150680) using 0.5% (w/v) agarose (VWR, PA, USA; cat no. MPN605) (dissolved in ultra-pure ddH<sub>2</sub>O) as an immobilization medium. Upon polymerization of the agarose, ~1 mL of ScaleS1 solution was pipetted into the culture plates to ensure coverage and adequate hydration of immobilized samples. Samples were individually imaged using an Olympus MPE-RS TWIN multiphoton microscope outfitted with dual excitation lasers (Spectra Physics INSIGHT DS+ -OL pulsed IR LASER, tunable from 680 to 1,300 nm, 120 fs pulse width at specimen plane and SPECTRA PHYSICS MAI TAI HP DEEP SEE-OL pulsed IR LASER, tunable from 690 to 1,040 nm, 100 fs pulse width at specimen plane). We have established optimal parameters for multiphoton microscopy in a previous study (Szabo-Pardi et al., 2019). In brief, using these excitation lasers in combination with a XLPLN25XWMP2 Olympus ultra 25 × MPE water-immersion objective (1.05 NA, 2 mm WD) we were able to image tdTomato-positive LysM<sup>+</sup> cells (LysM<sup>tdT+</sup>) (1,100 nm). Tissues were scanned using a galvanometer scanning unit at 10 us/pixel; 1:1 aspect ratio; 0.5 step size; 512 × 512 area and images were acquired with 2-channel multi-alkali photomultiplier tubes (PMTs). Z-stack images were acquired of the entire sample (Y-plane) of the DRG and distal/proximal portions of the ScN. A step size of 1 um per slice was used

and images were between 300 and 400 slices. FVMPE-RS system software (FluoView) was used to acquire images. Raw Z-stack images were then exported to Imaris imaging software for appropriate processing and analysis. Images were acquired by a blinded experimenter.

### **Image Analysis**

Analysis of ScN and DRG tissues LysM<sup>tdT+</sup> labeled macrophages was done with Imaris Software (Oxford Instruments, version 9.0.1). Previously acquired z-stacks are put into Imaris where each pixel from the 2D section was converted into a 3D voxel. This information was then used to reconstruct the original 3D object that spanned across the z-stacks. Images were imported into Imaris's Arena and viewed within the 3-D view of the Surpass. The Surfaces visualization is a computer-generated representation of the specified gray value range in the data set. In order to visualize the range of interest of an object's volume, an artificial solid object is created from which measurements can be derived. Surfaces were created using background subtraction for td-Tomato positive cells in the Z-stack images. A filter based on number of voxels was used to remove both artifacts and large neuronal cells within the image. Using the most representative image for DRGs and ScNs, creation parameters were made using the corresponding creation wizard in Imaris's Surfaces feature. Surfaces of the LysM<sup>tdT+</sup> macrophages were then measured for cell count, ellipticity, volume, and sphericity. In order to normalize cell count via volume of tissue, surfaces were created for the whole DRG and sections of ScN using absolute intensity thresholding. Both proximal and distal sections of ScN were analyzed and data points were labeled accordingly to determine spatial differences in macrophage infiltration and activation along the ScN. All analyses were performed by an experimenter blinded to sex, genotype, treatment, and tissue type.

1. Sphericity—Given as a value from 0.01 to 1.00 with 1.00 being a perfect sphere in which the x, y, and z axes are all equal length. The sphericity of a particle is the ratio of the surface area of an equal-volume sphere to the actual surface area of the particle. The closer to 0 this value is the less spherical and more ellipsoid the shape is.

2. Prolate ellipticity—Given as a value from 0.01 to 1.00 with 1.00 representing an ellipsoid with one axis significantly longer than the others. A prolate ellipticity value moving toward 0 represents the lengths of the x, y, and z axes becoming more even. Values closer to 0 represent a more spherical shape while values closer to 1 represent a more elongated shape. A more elongated shape is typically associated with an M2 phenotype.

3. Oblate ellipticity—Given as a value from 0.01 to 1.00 with 1.00 representing an ellipsoid with two axes equal in length but longer than the third. An oblate ellipticity value moving toward 0 represents the lengths of the x, y, and z axes becoming more even. Values closer to 0 represent a more spherical shape while values closer to 1 represent a more flattened shape. A more flattened shape is typically associated with an M1 phenotype.

### **Statistical Analysis**

Prism 8.01 software (GraphPad, San Diego, CA, USA) was utilized to generate all graphs and statistical analysis. Single comparisons were performed using Student's *t*-test, and multiple comparisons were performed using a one-way or two-way ANOVA with Bonferroni *post-hoc* tests for across-group comparisons. All data are represented as the standard error of the mean (SEM).

A  $p$ -value of  $<0.05$  was used to determine statistical significance. Blinded experimenters performed all experiments and analysis.

## **RESULTS**

### **Use of Interdisciplinary Techniques to Investigate the Macrophage Response During Peripheral Nerve Injury**

Macrophages are implicated in the development of pain following nerve injury and have complex immunologic, neurologic, and physical facets (Raouf, 2018). To improve our understanding of the dynamic immune response after peripheral nerve injury, we designed an interdisciplinary approach combining advanced multiphoton microscopy, *ScaleS1* tissue clearing and a well-established nerve injury model (SNI) Using these techniques, we were able to address some of the limitations of previous studies investigating the macrophage response to nerve injury. Primarily, these limitations include: a lack of appropriate male and female representation in data sets, an inability to assess morphological changes in macrophages while preserving the integrity of the microenvironment, and skewed information resulting from single-slice imaging analysis as opposed to whole tissue. While these studies greatly improve our understanding on the dynamic nature of macrophage recruitment and activation, they highlight a need to develop integrative techniques to improve our approach.

### **Male and Female Mice Exhibit Robust Pain Behaviors Following SNI**

To adequately assess the macrophage response to nerve injury, spared nerve injury (SNI) was performed to induce a pain state in both sexes. We chose this specific model of neuropathic pain because it has been shown to cause prolonged changes in behavioral phenotypes as well as immune

cell activation (Raouf, 2018). Moreover, the etiology of neuropathic pain that develops after SNI closely mimics the cardinal symptoms of clinically described neuropathic pain (Chen, 2015). In order to confirm that our procedure induced a pain state, we assessed mechanical hypersensitivity and cold allodynia in mice that received either SNI or sham. As expected, we found that males that received SNI exhibited significantly reduced paw withdrawal thresholds on days 1, 3 and 5 as compared to their sham counterparts. We report similar results in females where mice that received SNI had significantly reduced paw withdrawal thresholds on day 1, 3, and 5 as compared to sham controls (Figures 3.1A,C). Moreover, male mice that received SNI exhibited an elevated behavioral response to application of acetone to the ipsilateral hind paw on days 3 and 5 as compared to their sham counterparts. Similarly, female mice that received SNI exhibited an elevated behavioral response to application of acetone to the ipsilateral hind paw on days 1, 3, and 5 as compared to sham controls (Figures 3.1B,C). Lastly, we find no significant sex differences in the onset of mechanical hypersensitivity or cold allodynia after SNI. Taken together, these data indicate SNI induced robust pain behaviors before, and up to the day mice were euthanized and tissues were collected for analysis.

**Figure 3.1. Development of neuropathic pain behaviors following SNI.** Male and female  $LysM^{tdT+}$  mice were tested for mechanical hypersensitivity and cold allodynia on days 1, 3, and 5 post-SNI. (A) Male ( $n = 7$ ) and Female ( $n = 7$ )  $LysM^{tdT+}$  mice exhibit significantly reduced mechanical withdrawal thresholds post-SNI as compared to their respective sham controls ( $n = 7$ ). (B) Male ( $n = 7$ ) and Female ( $n = 7$ )  $LysM^{tdT+}$  mice exhibit significantly elevated response latency to acetone application as compared to their respective sham controls ( $n = 7$ ). (C) Graphical representation of the experimental timeline where male ( $n = 7$ ) and Female ( $n = 7$ )  $LysM^{tdT+}$  mice were given SNI and were assessed for mechanical hypersensitivity and cold allodynia on days 1, 3, and 5 post-SNI. \* $p < 0.05$ ; \*\*\* $p < 0.001$ ; \*\*\*\* $p < 0.0001$ . ### SNI Induces Macrophage Recruitment, Activation, and Morphological Changes in the DRG

To explore our initial hypothesis regarding sex differences in macrophage infiltration, lumbar DRGs (L4-5) were harvested from male and female  $LysM^{tdT+}$  reporter mice 5 days post-SNI. We integrated *ScaleS1* whole tissue clearing with multiphoton imaging in both male and female DRGs

to visualize macrophage recruitment, activation, and changes in morphology (Figure 3.2A). Imaris image analyses revealed significant differences in macrophage recruitment to the DRG following SNI. We found that injured (SNI) male ipsilateral DRGs displayed significantly increased amounts of  $\text{LysM}^{\text{tdT}^+}$  macrophages compared to the contralateral (uninjured) DRGs. Moreover, SNI induced significantly elevated  $\text{LysM}^{\text{tdT}^+}$  macrophage recruitment to the ipsilateral DRG as compared to the sham surgery. Surprisingly, we do not report a significant increase in  $\text{LysM}^{\text{tdT}^+}$  macrophage recruitment to the ipsilateral DRG in female mice after SNI. This remains true in the sham groups as well (Figure 3.2C). To account for differences in resident and infiltrating macrophages, we assessed the ratio of  $\text{LysM}^{\text{tdT}^+}$  macrophages in the ipsilateral (injured) DRG with the contralateral (uninjured) DRG. Again, we found that males display significantly upregulated  $\text{LysM}^{\text{tdT}^+}$  macrophages to the ipsilateral DRG. This is indicative of an upregulation of infiltrating macrophages (Figure 3.2D). To better understand the activation states of these infiltration macrophages, we analyzed the distribution and relative frequencies of  $\text{LysM}^{\text{tdT}^+}$  macrophage volumes after SNI. We report no significant findings; however, male mice exhibit a trend of larger cell volumes in the injured ipsilateral DRG (Figures 3.2B,E,F). While these findings are not statistically significant, considered with the robust recruitment of  $\text{LysM}^{\text{tdT}^+}$  macrophages, we can conclude that there is a biologically relevant upregulation and activation of macrophages in the DRG following SNI in male mice.

**Figure 3.2. Infiltration of  $\text{LysM}^{\text{tdT}^+}$  macrophages in the lumbar DRGs 5 days post-SNI.** Male and female  $\text{LysM}^{\text{tdT}^+}$  mice had DRGs harvested 5 days post-SNI. Tissues were processed and cleared using ScaleS1 solution for 10–14 days and imaged using 2-photon microscopy. (A) Representative images from male and female  $\text{LysM}^{\text{tdT}^+}$  (red; 1,100 nm) DRGs ( $n = 3$ ). (B) Frequency distribution histogram comparing the frequencies of  $\text{LysM}^{\text{tdT}^+}$  cell volumes in control and injured male and female lumbar DRGs. (C) Quantification of  $\text{LysM}^{\text{tdT}^+}$  macrophage infiltration in the lumbar DRGs 5 days post-SNI ( $n = 3$ ) in males and females. (D) Quantification of  $\text{LysM}^{\text{tdT}^+}$  macrophage infiltration in the lumbar DRGs 5 days post-SNI as a ratio of ipsilateral over contralateral DRG ( $n = 3$ ) in males and females. (E) Quantification of  $\text{LysM}^{\text{tdT}^+}$  macrophage volume in the lumbar DRGs 5 days post-SNI ( $n = 3$ ) in males and females. (F) Quantification of  $\text{LysM}^{\text{tdT}^+}$  macrophage cell volumes in the lumbar DRGs 5 days post-SNI as a ratio of ipsilateral over contralateral DRG ( $n = 3$ ) in males and females. \*  $p < 0.05$ ; \*\*  $p < 0.01$ . Scale Bar: 100  $\mu\text{m}$ . IP, Ipsilateral; CO, Contralateral. Made using BioRender.com.

Next, we wanted to identify changes in macrophage morphology after SNI as these changes can be correlated with shifts in pro-(M1) and anti-(M2) inflammatory polarization. Macrophages have been shown to play a key role in regulating homeostasis and tissue repair after nerve injury, and polarization plays an integral role in this process (Chernykh, 2016). We may map changes in geometric profiles of macrophages using measures of oblate (flattened) ellipticity, prolate (elongated) ellipticity, and sphericity (Iwata, 2017). In response to physiologic input and cytokine signaling, M2 polarized macrophages are associated with an elongated, prolate morphology while M1 macrophages are associated with an oblate, flattened morphology (Bertani, 2017). Drawing upon these recent discoveries and classifications, we assessed the geometrics of these recruited  $\text{LysM}^{\text{tdT}^+}$  macrophages in the DRG using Imaris analysis (Figure 3.3A). We found differences in the clustering of  $\text{LysM}^{\text{tdT}^+}$  macrophages in mice that received SNI, which take on a more oblate (flattened) morphology after nerve injury. This is indicative of an M1 polarized phenotype. Moreover, we found that  $\text{LysM}^{\text{tdT}^+}$  macrophages in animals that received a sham surgery take on a more prolate (elongated) morphology. This is indicative of an M2 polarized phenotype (Figure 3.3C). Lastly, we assessed sphericity of  $\text{LysM}^{\text{tdT}^+}$  macrophages after nerve injury (Figure 3.3B). Although we find no significant differences, cells that take on a more prolate (flattened) shape after injury are also more spherical, indicating a more active phenotype (Sen, 2016). Taken together, we conclude that macrophages have a dynamic morphological response to injury and may be characterized based on their geometric shape.

**Figure 3.3. Morphology of  $LysM^{tdT+}$  macrophages in the lumbar DRGs 5 days post-SNI.** Male and female  $LysM^{tdT+}$  mice had DRGs harvested 5 days post-SNI. Tissues were processed and cleared using ScaleS1 solution for 10–14 days and imaged using 2-photon microscopy. (A) Representative morphology from male and female  $LysM^{tdT+}$  (red; 1,100 nm) DRGs ( $n = 3$ ). (B) Imaris analysis of  $LysM^{tdT+}$  cell morphology in male and female DRGs. Cells were analyzed for three morphologic parameters (sphericity, prolate, and oblate) and are displayed comparing oblateness and prolateness with respect to sphericity. (C) Scatter plot of DRG  $LysM^+$  cell oblateness with respect to prolateness in both male and female injury and control groups. \*\*  $p < 0.01$ ; \*\*\*  $p < 0.001$ . Scale Bar: 100  $\mu$ m. IP, Ipsilateral; CO, Contralateral.

### SNI Induces Dynamic Changes in Macrophage Morphology in the ScN

To further identify the dynamic role of macrophages in response to nerve injury, we looked closer to the site of injury in the ScN. Here, we sought to distinguish the  $LysM^{tdT+}$  macrophage response between the DRG and ScN. Using the same principles, whole ScNs were harvested from male and female  $LysM^{tdT+}$  mice 5 days after SNI and were cleared using ScaleS1. Tissues were cleared and

imaged using multiphoton imaging and tissues were analyzed using Imaris (Figure 3.4A). Analyses revealed no significant differences in  $\text{LysM}^{\text{tdT}^+}$  macrophage recruitment to the distal or proximal ScN. Although, both male and female mice exhibit elevated  $\text{LysM}^{\text{tdT}^+}$  macrophages in the ipsilateral ScN as compared to the contralateral control. While not significant, this does indicate a surgery-induced upregulation in macrophage recruitment to the ScN in males and females (Figures 3.4C, D). We report no differences in the volumes of these recruited  $\text{LysM}^{\text{tdT}^+}$  macrophages (Figure 3.4D). Moreover, we do not report any differences in the distribution or relative frequencies of  $\text{LysM}^{\text{tdT}^+}$  macrophage volumes after SNI in the ScN. However, female mice exhibit a larger distribution of  $\text{LysM}^{\text{tdT}^+}$  cell volumes after SNI in the ipsilateral ScN as compared to other groups, indicating increased classical activation of macrophages (Figure 3.4B). Lastly, we report no differences in the cell volumes of  $\text{LysM}^{\text{tdT}^+}$  macrophages in the ScN after SNI in both males and females (Figures 3.4E,F). Taken together, we can conclude there are dynamic biological changes that occur in the ScN following SNI in males and females.

**Figure 3.4. Infiltration of  $LysM^{tdT+}$  immune cells in the ScNs 5 days post-SNI.** Male and female  $LysM$ -cre  $\times$   $tdTomato$  mice had ScNs harvested 5 days post-SNI. Tissues were processed and cleared using ScaleS1 solution for 10–14 days and imaged using 2-photon microscopy. (A) Representative images from male and female  $LysM^{tdT+}$  (red; 1,100 nm) ScNs ( $n = 3$ ). (B) Frequency distribution histogram comparing the frequencies of  $LysM^{tdT+}$  cell volumes in control and injured male and female lumbar ScNs. (C) Quantification of  $LysM^{+}$  immune cell infiltration in the lumbar ScNs 5 days post-SNI ( $n = 3$ ) in males and females. (D) Quantification of  $LysM^{tdT+}$  macrophage infiltration in the lumbar ScNs 5 days post-SNI as a ratio of ipsilateral over contralateral ScN ( $n = 3$ ) in males and females. (E) Quantification of  $LysM^{tdT+}$  macrophage volume in the lumbar ScNs 5 days post-SNI ( $n = 3$ ) in males and females. (F) Quantification of  $LysM^{tdT+}$  macrophage cell volumes in the ScN 5 days post-SNI as a ratio of ipsilateral over contralateral ScN ( $n = 3$ ) in males and females. Scale Bar: 100  $\mu$ m. IP, Ipsilateral; CO, Contralateral. Made using BioRender.com.

We incorporated our geometric analyses to better understand the morphological changes that may occur in macrophages in the ScN (Figure 3.5A). While we report no differences in recruitment, there may be morphological changes that are biologically relevant (Cobos, 2018). We investigated

the sphericity of LysM<sup>tdT+</sup> macrophages in the ScN and found that there were no differences between sexes or injury. Typically, a more spherical, or round, macrophage is classically activated, however, this does not mean that these macrophages have not altered their contractile state in response to injury. We report that there is a sexual dimorphism in the morphology of LysM<sup>tdT+</sup> macrophages in the sciatic nerve 5 days after SNI. Male LysM<sup>tdT+</sup> macrophages on the injured side exhibit more oblate, or flattened, cell morphology as opposed to females that exhibit a more prolate, or elongated, cell morphology (Figure 3.5C). This is indicative of an M1 polarization state in males as opposed to an M2 state in females. This idea has been a dogma in the field of neuroimmunology for decades (Li, 2009). Lastly, we find no differences in the sphericity of LysM<sup>tdT+</sup> macrophages in the ScN (Figure 3.5B). This data indicates a distinction in macrophages in the DRG vs. ScN, where DRG macrophages are more M1 polarized in both sexes after surgery, and ScN macrophages are M1 polarized in males vs. M2 polarized in females.

**Figure 3.5. Morphology of  $LysM^{tdT+}$  macrophages in the ScN 5 days post-SNI.** Male and female  $LysM^{tdT+}$  mice had ScNs harvested 5 days post-SNI. Tissues were processed and cleared using ScaleS1 solution for 10–14 days and imaged using 2-photon microscopy. **(A)** Representative morphology from male and female  $LysM^{tdT+}$  (red; 1,100 nm) ScNs ( $n = 3$ ). **(B)** Imaris analysis of  $LysM^{tdT+}$  cell morphology in male and female ScNs. Scale Bar: 100  $\mu$ m. IP, Ipsilateral; CO, Contralateral.

## DISCUSSION

Whole tissue *in-situ* visualization can reveal neuroimmune interactions that have been overlooked in the past. The goal of the present study was to analyze the sex-dependent dynamics of macrophage recruitment and changes in morphology after injury utilizing next generation tissue

clearing and imaging techniques. We performed SNI on male and female transgenic reporter mice constitutively expressing tdTomato, a red fluorescent protein, in macrophages under the LysM promoter. We then harvested lumbar DRGs and ScNs from these animals 5 days after the surgery and optically cleared the tissues using *ScaleS1*. Macrophage recruitment and subsequent expansion peaks between days 3 and 7 after injury, therefore we chose day 5 to assess their physical characteristics (Chen, 2015). We then acquired high resolution Z-stack images of the cleared tissues using multiphoton microscopy and performed extensive analyses using Imaris Imaging Software to understand the dynamics of macrophage recruitment, activation, and morphology after injury. In this study, we found that males have higher LysM<sup>tdT+</sup> macrophage counts in the lumbar DRGs (L4/5), expanding upon current literature that suggests females have alternative neuroimmune mechanisms that contribute to pain states. Moreover, we find dynamic changes in LysM<sup>tdT+</sup> macrophage morphology, with SNI inducing a more pro-inflammatory, or M1, phenotype measured by cell shape (Figure 3.6). This highlights the need to improve our understanding of the sex-dependent distribution and role of other immune cells in pain. From a therapeutic perspective, there is a potential to harness the abilities of macrophages to induce anti-nociception and tissue repair after injury (Yu et al., 2020). The vast majority of our current understanding in macrophage functionality is reliant on soluble factors, such as cytokine production and cell surface protein expression. While this information is useful in providing the necessary framework to investigate the molecular underpinnings of macrophage activation in response to injury, bridging the gap between functionality and physical characteristics will discern the full spectrum of their involvement in tissue injury.

**Figure 3.6. Graphical abstract representing the dynamic nature of macrophage recruitment and morphological changes following SNI in males and females.**

Bi-directional communication between neuronal and non-neuronal cells in the DRG is a core mechanism in mediating the mammalian response to injury (Lopes, 2017). Current literature highlights the complex role that macrophages play in regulating inflammation and pro-nociception following injury, but the relevant sites of action remains unclear (Echeverry, 2013). Moreover, the current dogma in the field dictates males utilize a myeloid cell driven mechanism of neuronal sensitization to drive neuroinflammation (McWhorter, 2013). Although the reported behavioral contribution of these DRG macrophages is not dimorphic in nature, there exists a key cellular difference in their recruitment and morphology, leading to the idea that etiology differences can influence pain perception over time. Our data shows the magnitude of injury-induced macrophage expansion in the lumbar DRGs is significantly higher in males than in females. These findings are

also supported by a paper that characterizes sex differences in immune cell recruitment to both central and peripheral nervous tissues through flow cytometric analyses (Mosser, 2008). They demonstrate an upregulation of macrophages in both males and females after peripheral nerve injury in the lumbar DRGs, with key sex differences in the adaptive immune response. However, the adaptive immune response to injury was not the focus of our study. Collectively, these studies support the idea that macrophage recruitment to the DRG plays a critical role in neuroinflammation. Furthermore, we utilized sham and contralateral data to determine that no conclusive sex differences exist in baseline cell size and volumes further strengthening our premise that immune response to injury is sex dependent.

Conflicting reports about the role of macrophages in the ScN after nerve injury has groups reporting that macrophages do not play an important role in the pathogenesis of nerve injury-induced pain (Yu, 2020), while other reports found that inhibiting local macrophages in the ScN impairs development of neuropathic pain following nerve injury (Paul, 2013). An important distinction here is that we assessed the recruitment and morphological changes in macrophages at both distal ScN and proximal ScN. Here we assessed differences in macrophage activity with more granularity than previous studies. We find no significant recruitment of LysM<sup>tdT+</sup> macrophages in the ScN 5 days after SNI, however, this does not equate to a lack of biological significance. It is a potential that the differences in macrophage morphology after SNI may alter cytokine signaling. Certain M2 macrophages phenotypes, or cells that have an elongated shape, retain the ability to produce pro-inflammatory cytokines and may be a differentiating factor in the immune response to injury in males vs. females (De Paoli et al., 2014). Despite our collective efforts, a rift exists in

our understanding of the role of macrophages in the ScN, but with every advance we are able to better understand the nuances of macrophages recruitment, activation and subsequent biological implications.

While the aforementioned studies have significantly improved our understanding of the dynamic nature of macrophage recruitment to peripheral nervous tissues, they have inherent limitations that we have addressed using our model. Geometric alteration of macrophages in response to injury has the ability regulate their functional phenotype (Tauer, 2002). However, it is impossible to discern this type of information by using typical immunohistochemical or flow cytometric analyses. Macrophages exhibit an elongated shape when polarized to an M2 phenotype, as opposed to a flattened shape when polarized to an M1 phenotype (Bronte, 2015). These polarization states are involved in a myriad of biological processes related to inflammation and tissue repair and are often indicative of a macrophages change in contractility as they interact with the extracellular matrix and cell adhesion molecules (Jensen, 2017). *In vivo* these polarization states are not dichotomous, but targeted therapeutics may be better tailored to treat each sex individually. Moreover, traditional imaging acquisition and analysis techniques are not well-suited to investigate changes in cellular shape as there are significant limitations in the resolution and depth of acquired images. This severely dampens the ability of researchers to utilize common image analysis software for this purpose. Therefore, we sought to address this lack of granularity by improving our understanding of the physical characteristics of macrophages in response to nerve injury utilizing Imaris image analysis (Belle, 2017).

Optical clearing techniques provide additional clarity in resolving cell to cell interactions by circumventing the limitations of traditional 2-dimensional (2-D) imaging. Typically, 2-D image reconstruction of limited z-frames provides biased information as cellular density is not uniform throughout select regions of interest. By using *ScaleS1* optical tissue clearing in combination with deep tissue multiphoton microscopy, we were able to create a 3-D model of whole DRGs and ScNs. This allowed us to accurately assess the infiltration of immune cells to these tissues following peripheral nerve injury. Multiphoton microscopy may be used to image thicker tissue slices, but image quality quickly deteriorates when focusing deeper into a sample (Renier, 2014). To circumvent this limitation, we chose to utilize *ScaleS1* as our method of optical tissue clearing. *ScaleS1* was our preferred method of optical tissue clearing as it has been shown to avoid tissue expansion, preserve lipids and provide a safe immersion-medium for objectives (Hama, 2015). We also took into consideration other clearing methods, such as DBE or CLARITY. These alternate clearing methods offered a shorter clearing time and work better on larger tissue sizes, however they had considerable limitations with regard to preservation of fluorescence and tissue integrity (Jensen, 2017). Another clearing method we considered was DISCO which utilizes a de-lipidating agent to enhance the refractory index of the tissue (Belle, 2017). Similar to previously discussed alternatives, this method allows for faster clearing times, however it is accompanied with significant amounts of tissue distortion making it suboptimal for our study. Current use of this method is better suited for larger tissues, such as brain or embryos (Renier, 2014). Furthermore, *ScaleS1* utilizes materials that are inexpensive and commonly found in research labs making it easy to use and more accessible to a wider audience. Moreover, *ScaleS1* is well-suited for imaging fluorescent proteins, which was the primary focus of our study.

In conclusion, the combined use of our genetic model, tissue clearing, and multiphoton microscopy serves as a powerful tool for investigating neuroimmune spatiotemporal relationships and provides a versatile framework to further our understanding of the role macrophages play in pain development. Moreover, we further delineate the sexual dimorphisms that exist in the physical phenotype of macrophages in response to nerve injury.

## **CHAPTER 4**

# **SEX DIFFERENCES IN PACLITAXEL-INDUCED NEUROPATHIC PAIN ARE DRIVEN BY TLR4 SIGNALING ON MACROPAGES**

## ABSTRACT

Chemotherapy-induced peripheral neuropathy (CIPN) persists in over a third of patients exposed to chemotherapeutics and is linked to the generation of chronic pain long after cessation of treatment. While paclitaxel activates toll like receptor 4 (TLR4) on macrophages, the sex-specific mechanisms of macrophage activation during chemotherapy treatment and its effects on both behavioral and molecular pain phenotypes remains elusive. Uncovering how cells recognize and respond to chemotherapeutics will lead to improved understanding of the mechanisms in pain plasticity and ultimately better therapies. We hypothesized that activation of TLR4 on macrophages facilitates a sex-dependent transition in the cellular machinery required to establish neuropathic pain during chemotherapy. In this study, we used  $\text{LysM}^{\text{TLR4}^{\text{FloX}}}$  mice which allow for cre-mediated deletion of a floxed TLR4 allele by utilizing cre-recombinase in the LysozymeM promoter in peripheral macrophages. Therefore, we are able to assess the role of TLR4 activation on macrophages during systemic paclitaxel treatment. Interestingly, we observed a reversal of mechanical hypersensitivity when TLR4 is removed from macrophages in males, but not females. Moreover, we found that paclitaxel drives a shift towards a pro-inflammatory cellular phenotype in male macrophages. We identified an increase in dorsal root ganglia (DRG) macrophages and neuronal activating transcription factor 3 (ATF3) expression after paclitaxel treatment in both sexes. These increases are dependent on macrophage TLR4 in males only. Lastly, we observed a reduction in hind paw intraepidermal nerve fiber density following paclitaxel treatment in both sexes, however; this effect is reversed only in male macrophage TLR4 knockouts. Taken together, this work demonstrates a sex-specific effect on macrophage TLR4 in paclitaxel-induced peripheral

neuropathy; highlighting the need to delve deeper to uncover the mechanisms behind sex differences observed in the promotion of chronic pain states.

## **INTRODUCTION**

Chemotherapy-induced peripheral neuropathy (CIPN) is one of the major dose-limiting side effects of chemotherapy treatment in cancer patients (Oun et al., 2018). Patients often report pain and numbness, coined “pins and needles” by many physicians, in the affected extremities (Wolf et al., 2012). More than 70% of cancer patients present with these symptoms in the clinic during routine treatments, which often predicates poor disease prognosis (Seretny et al., 2014). Moreover, exposure to chemotherapeutics is closely linked to neural plasticity underlying chronic pain long after cessation of treatment, making CIPN a long-term morbidity in many cancer survivors (Hershman et al., 2016). Therefore, elucidating the sex-specific mechanisms that regulate the development of CIPN may present a point of personalized therapeutic intervention in which pain comorbidities may be alleviated, allowing for extended periods of chemotherapy regimens and significantly improved quality of life.

With 2015 NIH mandate necessitating the inclusion of sex as a biological factor in peer-reviewed studies, there has been a marked improvement in the quality of studies in pain research. This recent renewal has shed light on discoveries which suggest the neuroimmune mechanisms that regulate chronic pain between sexes is varied (Mogil, 2020). Conversely, inconsistencies in both clinical and pre-clinical literature investigating sex differences during CIPN development highlight the dire need for comprehensive studies aimed at effectively dissecting the complex nature of CIPN

(Gewandter et al., 2020; Najj-Esfahani et al., 2016). One of the most broadly prescribed chemotherapeutic agents used to treat solid tumors is paclitaxel, an antineoplastic agent, which primarily acts through microtubule destabilization and cell-cycle arrest (Zhu & Chen, 2019). Interestingly, an alternative mechanism of paclitaxel treatment engages inflammatory signaling through toll like receptor 4 (TLR4), similar to lipopolysaccharide (LPS) (Byrd-Leifer et al., 2001). We recently published a study that demonstrates cap-dependent protein translation, regulated by eukaryotic translation initiation factor 4E (eIF4E), possesses a pivotal role in paclitaxel-induced neuropathy development, with nuanced sex- and cell-specific differences (Agalave et al., 2021; Megat et al., 2019). Specifically, T-cell subpopulations in the lymph nodes are dysregulated after paclitaxel treatment and are modulated by expression eIF4E. These physiological changes attenuate nociceptive behavioral phenotypes in response to paclitaxel treatment in both sexes. This suggests that inflammatory signaling pathways mediated by the eIF4E complex, many of which are downstream of TLR4 activation, are closely involved in pain plasticity during chemotherapy treatment.

Not unlike T-cells, macrophages have been shown to regulate pain and inflammation in a sex-dependent manner (Yu et al., 2020). As part of the innate immune system, macrophages can adopt diverse functional phenotypes in response to stimulation. These shifts in cellular phenotypes can be attributed to their expression of M1 or M2 biomarkers, and can represent a broad spectrum of opposing biological functions (Murray, 2017). M1 macrophages exhibit pro-inflammatory properties, such as upregulated cytokine production, antigen presentation, and phagocytic activity, whereas M2 macrophages are more anti-inflammatory in nature and promote tissue regeneration

through immunosuppression (Mendoza-Coronel & Ortega, 2017). A driving force in macrophage polarization is the activation of pattern recognition receptors (PRRs), which possess a crucial role in initiating the innate immune response to infection and tissue injury (Srivastava et al., 2017). TLR4, a PRR, has been implicated in numerous studies investigating the effects of chemotherapeutics on CIPN development (Li et al., 2014; Rajput et al., 2013; Son et al., 2019). Activation of TLR4 on male macrophages by paclitaxel treatment induces pro-inflammatory polarization and prevents anti-inflammatory polarization (Wanderley et al., 2018). Dysregulated inflammation from macrophages in the dorsal root ganglia (DRG), specifically, can influence the activity of nociceptors through release of inflammatory mediators in response to paclitaxel treatment (Zhang et al., 2016). Reciprocal interaction between these two populations could contribute to maladaptive nociceptor plasticity during CIPN development. An inherent limitation in many of the previously mentioned studies is the lack of female representation. Although the incidence and mortality of cancer is higher in men than women, understanding the mechanisms that contribute to CIPN, a major dose-limiting side effect of chemotherapeutics, would allow for more personalized therapeutics and improved disease prognoses for both men and women (Kim et al., 2018).

Therefore, we sought to elucidate the sex-specific role of TLR4 activation during CIPN which may mediate crosstalk between activated immune and neuronal populations in the DRG. We utilized LysozymeMcre  $\times$  TLR4<sup>fl/fl</sup> (LysM<sup>TLR4Fllox</sup>) mice as a genetic tool, which allow for cre-mediated deletion of a floxed TLR4 allele by utilizing LysM as a promoter for cre expression in macrophages and monocytes, specifically (Jia et al., 2014). Given the lack of studies adequately powered to

assess sex differences in CIPN, we investigated if there was a sex-dependent role of TLR4 activation during paclitaxel-induced neuropathic pain development, phagocytic capacity of macrophages, and intraepidermal nerve fiber (IENF) density in the paw skin. We hypothesized that paclitaxel regulates activation of macrophages through TLR4 signaling in males, which facilitates dysregulated communication between these cells and nociceptive neurons in the DRG. These bi-directional inflammatory signaling processes promote inflammatory polarization and antigen presentation in male macrophages, which leads to upregulated incidence of neuronal injury, retraction of IENFs and subsequent CIPN development.

## **MATERIALS AND METHODS**

### **Animals**

All experiments utilizing animals were performed accordance with ARRIVE guidelines and the National Institutes of Health guide for the care and use of Laboratory animals (NIH Publications No. 8023, revised 1978). Adult male and female mice between 8 and 14 weeks old (20-30g weight) were used for all behavioral and molecular experiments; a general timeline is detailed in Figure 4.1. In this study we utilized LysozymeMcre  $\times$  TLR4<sup>fl/fl</sup> mice as a genetic tool to dissect the cell-specific role of TLR4 on myeloid cells. In brief, these mice allow for cre-mediated deletion of a floxed TLR4 allele in macrophages and monocytes by utilizing LysM as a promoter for expression of a cre recombinase enzyme (Figure 4.2A). These mice were originally obtained as a generous gift from by Dr. Joel Elmquist's laboratory at UT Southwestern but are also commercially available from Jackson Laboratory (Jia et al., 2014). Animals were bred in house to maintain the transgenic line and pups were weaned between 21-28 days old, ear notched, and tail-clipped to

verify genotypes *via* polymerase chain reaction (PCR) (Figure 4.2B). All animals used in this study were homozygous for the TLR4<sup>Flox</sup> gene. Cell-specific knockout mice, LysM<sup>TLR4Flox</sup>, were heterozygous for the LysMcre gene; littermates WT for cre were used as wild type controls. Mice were group housed with 4-5 animals per cage (separated by sex at the time of weaning) in a temperature-controlled vivarium (20-25°C) and a 12-hour light/dark cycle (6 am-6 pm) with *ad libitum* access to standard rodent chow and water. Experimenters were blinded to sex (except for behavioral experiments), genotype, and treatment during behavioral testing, cell culture, tissue freezing, cryosectioning, staining, histological procedures, and image acquisition and image analysis.

## **Drugs**

Stock paclitaxel (Sigma-Aldrich, T1912) was reconstituted at 5mg/ml in a 1:1 ratio of kolliphor oil (Sigma-Aldrich, C5135) and 100% ethanol (Thermo Fisher Scientific, 2701) (vehicle) and stored at 4°C until further use. Prior to administration, a working solution was prepared fresh by diluting the stock solution in 1× phosphate-buffered saline (PBS) (Thermo Fisher Scientific, BP3994). Animals received a 4 mg/kg intraperitoneal injection of paclitaxel every other day for a total of 4 injections and a total dose of 16 mg/kg (Toma et al., 2017). Vehicle treatments consisted of a 1:1 ratio of kolliphor oil and 100% ethanol were diluted in 1× PBS. Following injection, animals were closely monitored for signs of pain, illness, and bleeding and euthanized if in poor health (<1%).

## **Behavioral Experiments**

Baseline readings for all behavioral assays were recorded before animals were randomly assigned to treatment groups based on sex and genotype. In brief, mice were placed in custom built (11 cm length x 10 cm width x 4.5 cm height) clear acrylic behavior racks above a wire mesh grid. Mice were allowed to habituate for minimally 2 hours and all behavioral testing was performed between 8 am and 4 pm, during the light cycle. Mechanical hypersensitivity was measured by von Frey filaments (Stoelting, 58011) using the up-down method and cold allodynia was measured with biology grade acetone (Thermo Fisher Scientific, AI6P-4) using the acetone test (Chaplan, 1994; Yoon, 1994). Mechanical hypersensitivity is represented as the average paw withdrawal in grams, and cold allodynia is represented as the average response to application of acetone over the course of 60 seconds. Mechanical hypersensitivity was always assessed prior to cold allodynia. Upon completion of behavioral testing, mice were returned to their home cages and the behavior racks were thoroughly cleaned with a 1:3 ratio of a plant-based deodorant free solution (Seventh Generation, 22719BK).

Behavioral data sets are also represented as effect sizes. Effect sizes were determined by calculating the cumulative difference between the value for each time point and the subsequent baseline value (Agalave et al., 2021; Szabo-Pardi et al., 2021). Calculated values were summed to obtain the effect size, which is represented as an absolute number for each group (Hassler et al., 2020).

### **Peritoneal Macrophage Isolation, Culture and Treatment**

Naïve mice were deeply anesthetized with 100% isoflurane (Covetrus, 11695) and euthanized *via* cervical dislocation. Peritoneal macrophages were extracted by injecting 8 mL of sterile 1× PBS into the peritoneal cavity using a 27-gauge needle (BD, 305136) attached to a 10 mL syringe (BD, 300912). The peritoneal cavity was gently agitated for 30 seconds to dislodge macrophages adhered to the surface of organs. Four mLs of fluid from the peritoneum was then extracted using a 25-gauge needle (BD, 305122) attached to a 10 mL syringe, dispensed into a sterile 50 mL conical tube (VWR, 89039-658), and kept on ice. Isolated peritoneal macrophages were then spun down in a centrifuge for 4 min at 0.6 relative centrifugal force (RCF) to form a cell pellet. The remaining supernatant was decanted, and the cells were resuspended in 37°C RPMI media (Hyclone, SH30605) supplemented by 5% fetal bovine serum (FBS) (R&D Systems, S12495) and 1% penicillin-streptomycin (PS) (Thermo Fisher Scientific, 15070063). The cells were then counted using an automatic cell counter and 100,000 cells were seeded on poly-d-lysine coated coverslips (Sigma-Aldrich, P0899) in a 24 well plate (VWR, 10861-558). The cultures were then stored at 37°C in a humidified incubator and maintained to obtain 80% cellular confluency, after which macrophages were treated with 200 nM of paclitaxel (reconstituted as previously described), or vehicle (as previously described) diluted in 37°C RPMI supplemented with 1% FBS and 1% PS for 24 hours. Following paclitaxel treatment, 20  $\mu$ L ( $1.0 \times 10^8$ ) of opsonized fluorescein isothiocyanate (FITC) microbeads (1  $\mu$ m diameter) were dispensed into each well and the cultures were incubated at 37°C for 1 hour. After incubation, the cultures were washed three times with ice cold 1× PBS for 5 minutes each to stop phagocytic activity.

## **Immunocytochemistry**

The peritoneal macrophage cultures treated with FITC microbeads were fixed with 4% paraformaldehyde (PFA) (Sigma-Aldrich, 158127) for 30 minutes and washed thrice with 1× PBS for 5 minutes each. After washing, the fixed cultures were blocked for non-specific antibody binding and permeabilized at room temperature (RT) for 2 hours in a solution containing: 1× PBS, 2% heat-inactivated normal goat serum (NGS) (Gibco, 16210-072), 1% BSA, 0.1% triton X-100 (Sigma-Aldrich, X100), 0.05% tween-20 (Sigma-Aldrich, P1379), and 0.05% sodium azide (Sigma-Aldrich, RTC0000068). The blocked and permeabilized cultures were then incubated with a primary antibody cocktail diluted in the previously described buffer at 4°C for 24 hours (see Table 4.1). Incubated cultures were washed three times with 1× PBS at RT for 5 minutes each. After washing, cultures were incubated with a secondary antibody cocktail diluted in the previously described buffer at RT for 2 hours (see Table 4.1). Stained cultures were then washed once with 1× PBS at RT for 5 minutes and treated with DAPI solution (Sigma-Aldrich, D9542) at RT for 5 minutes. Stained coverslips were then washed three times with 1× PBS at RT for 5 minutes each and covered with Fluoroshield (Sigma-Aldrich, F6182) mounting medium and placed face down on a glass slide (Thermo Fisher Scientific, 12-544-7). Z-stack images for phagocytosis analysis and representation were taken using a Zeiss (Jena, Germany) Axio-Observer 7 epifluorescent microscope at 20x using 15 slices and a 1 μm step size. Light source power and exposure time were identical for all images used in quantitative analysis. Image analysis was performed using ImageJ version 1.53 (National Institutes of Health, Bethesda, MD) for Windows (Microsoft). In brief, phagocytic activity was measured *via* intracellular colocalization of FITC microbeads and cluster of differentiation 68 (CD68) positive cells. The Colocalization Image

Creator plugin was utilized to generate images measuring intracellular colocalization of fluorescent microbeads with CD68. Image thresholds were set and a 1  $\mu\text{m}$  particle size filter was used to isolate objects of interest. The 3D Object Counter plugin provided counts of the FITC microbeads and CD68 positive macrophages colocalized in each Z-slice, compounding colocalization measures across the entire image to obtain a final value (Lunde & Glover, 2020). Data are represented as the ratio of intracellular microbeads to the total number of CD68 positive macrophages on the analyzed image. Lastly, the numerical average across three technical replicates was calculated and graphed per animal used in the experiment.

### **Immunohistochemistry**

Ten days after paclitaxel treatment, mice were deeply anesthetized using 100% isoflurane and euthanized *via* cervical dislocation and subsequent decapitation. Lumbar (L3-5) DRG, and hind paws were isolated and collected in 4% PFA for 24 hours at 4°C and cryoprotected in 30% sucrose (Sigma-Aldrich, S0389) for minimally 48 hours at 4°C. DRG and paw skin were then embedded in optimal cutting temperature (OCT) medium (Thermo Fisher Scientific, 50-363-773) and cryosectioned at 16 and 20  $\mu\text{m}$ , respectively, and mounted on positively charged glass slides (Thermo Fisher Scientific, 12-550-15). Mounted sections were allowed to dry for 30 minutes before being stored at -20°C until further use. Prior to staining, mounted sections were thawed and dried at 30°C for 5 minutes. Slides were then blocked for non-specific antibody binding and permeabilized at RT for 2 hours in a solution containing: 1 $\times$  PBS, 2% heat-inactivated NGS, 1% BSA, 0.1% triton X-100, 0.05% tween-20, and 0.05% sodium azide. Slides were then incubated with a primary antibody cocktail diluted in the previously described buffer at 4°C for 24 hours (see

Table 4.1). Slides were washed three times with 1× PBS at RT for 5 minutes each. After washing, slides were incubated with a secondary antibody cocktail diluted in the previously described buffer at RT for 2 hours (see Table 4.1). Slides were then washed once with 1× PBS at RT for 5 minutes and treated with DAPI solution at RT for 5 minutes. Slides were then washed three times with 1× PBS at RT for 5 minutes each and covered with Fluoroshield mounting medium and a 1.5 mm glass coverslip (Thermo Fisher Scientific, 08-774-384). Z-stack images for DRG analysis and representation were taken using an Olympus (Tokyo, Japan) IX83 epifluorescent microscope at 20x using 15 slices and a 1 μm step size. Z-stack images for paw skin analysis and representation were taken using a Zeiss (Jena, Germany) Axio-Observer 7 epifluorescent microscope at 40x using 20 slices and a 1 μm step size. Light source power and exposure time were identical for all images used in quantitative analysis. Image analysis was performed using ImageJ version 1.53 (National Institutes of Health, Bethesda, MD) for Windows (Microsoft). In brief, CD68 and ATF3 upregulation in the DRG was analyzed by localization with DAPI. Image thresholds were obtained and a 5-100 μm particle filter was used to isolate objects of interest. In the DRG, data are represented as the ratio of CD68 positive cells to the total area (mm<sup>2</sup>) of the analyzed DRG, or the total number of ATF3 positive cells. The numerical average across two technical replicates was calculated and graphed per animal used in the experiment. Intraepidermal nerve fiber density in the paw skin was measured by tracing protein gene product 9.5 (PGP9.5) staining and counting the number of fibers that crossed the basement membrane (Kennedy et al., 1996). In the paw skin, data are represented as the density of PGP9.5 positive fibers to the total distance (mm) of the analyzed section of paw skin. The numerical average across three technical replicates was calculated and graphed per animal used in the experiment.

## Statistical Analysis

Data were assessed for statistical significance using GraphPad Prism software (version 9.3) and are expressed as mean  $\pm$  standard error of the mean (SEM), unless otherwise specified. For all data sets, three-way ANOVAs were performed followed by Sidak's *post-hoc* for multiple comparisons to appropriately assess sex, genotype, and treatment effects. A *p* value of  $< 0.05$  was considered statistically significant.

**Figure 4.1. Schematic of the experimental timeline used in this study.** Following habituation and behavioral baselines, mice were subjected to intraperitoneal injections of paclitaxel (4 mg/kg) on days: 0, 2, 4, and 6 to model CIPN. A subset of naïve mice was euthanized and used for peritoneal macrophages cultures and flow cytometry to assess phagocytic activity of cells after paclitaxel treatment. Behavioral assays (mechanical hypersensitivity and cold allodynia) were performed on days 7 to 35 after the start of paclitaxel treatment. A subset of mice was sacrificed on day 10 and peritoneal macrophages, lumbar DRG and hind paws were collected for flow cytometry and histology.

## RESULTS

### TLR4 signaling on Macrophages Mediates the Development of CIPN in males, but not Females.

It has previously been shown that paclitaxel, and many other chemotherapeutics, facilitate development of neuropathic behavioral phenotypes (Barginear et al., 2019; Staff et al., 2020). We asked whether TLR4 activation by paclitaxel on LysM positive macrophages was necessary for

the development of CIPN in both sexes, since paclitaxel is often used to treat metastatic breast cancer and is accompanied by dose-limiting pain comorbidities (Brady et al., 2021). To test this, we used a previously validated transgenic mouse line,  $LysM^{TLR4^{Fllox}}$ , which enabled us to selectively ablate TLR4 expression in peripheral macrophages and monocytes in a constitutive, cre-dependent manner (Figure 4.2B). Consistent with our previous study, and many others, male and female mice treated with a total dose of 16 mg/kg paclitaxel developed robust mechanical and thermal sensitivity by day 7, (Figure 4.2C-E, Table 2) (Agalave et al., 2021; Boyette-Davis et al., 2011; Li et al., 2017; Li et al., 2014; Zhang et al., 2016). Interestingly, removal of TLR4 from macrophages was associated with a protective behavioral phenotype, where development of mechanical but not thermal hypersensitivity in paclitaxel treated male mice was attenuated (Figure 4.2C & E, Table 2). This indicates that TLR4 signaling on macrophages is required for mediating the response to mechanical but not thermal stimuli after paclitaxel treatment in males. Conversely, we did not observe the same protective phenotype in female  $LysM^{TLR4^{Fllox}}$  mice. This implies that paclitaxel acts through a different receptor or cell population in females since development of nociceptive phenotypes in wild type mice is similar between sex (Figure 4.2D & E, Table 2). Taken together, our data suggest that activation of TLR4 on macrophages by paclitaxel, specifically in males, is an important mechanism involved in CIPN development.

**Paclitaxel increases phagocytic behavior of male, but not female macrophages in a TLR4-dependent manner.**

Measuring uptake of microbeads as a proxy of cell-to-cell signaling is an increasingly viable way to study mechanisms of macrophage biology, *in vitro* (Mohning et al., 2018). Paclitaxel has been

previously shown to significantly enhance phagocytic activity of macrophages derived from bone marrow, with recent evidence suggesting that TLR4 may regulate phagocytosis through one of its adaptor proteins, translocating chain-associated membrane protein (TRAM) (Li et al., 2008; Skjesol et al., 2019). It's possible that one mechanism of CIPN development is through interaction of paclitaxel and TLR4 to engage phagocytosis in macrophages. To test this hypothesis, we isolated and subsequently cultured peritoneal macrophages from male and female  $LysM^{TLR4^{Fllox}}$  mice. Upon reaching appropriate confluency, the cells were treated with paclitaxel for 24 hours and incubated with opsonized fluorescent beads for one hour to measure phagocytic behavior (Figure 4.3A). We discovered a robust sex difference where paclitaxel treatment significantly increases bead uptake in male, but not female wild type macrophages. Moreover, conditional deletion of TLR4 from these isolated macrophages only prevents the paclitaxel-induced upregulation of phagocytic behavior in males (Figure 4.3B; Table 4.3). This suggests that the direct action of paclitaxel on male macrophages induces a pro-inflammatory phenotype and are dependent on TLR4 signaling, whereas female macrophages are less affected by paclitaxel.

**Figure 4.3. Paclitaxel treatment induces phagocytosis of FITC microbeads in cultured macrophages by a sex- and genotype-dependent manner.** A) Representative image from a  $TLR4^{Flox}$  male treated with paclitaxel. Individual group sample sizes are as follows: Male Vehicle ( $TLR4^{Flox}$  n=3;  $LysM^{TLR4Flox}$  n=7), Male Paclitaxel ( $TLR4^{Flox}$  n=3;  $LysM^{TLR4Flox}$  n=7), Female Vehicle ( $TLR4^{Flox}$  n=4;  $LysM^{TLR4Flox}$  n=6), Female Paclitaxel ( $TLR4^{Flox}$  n=4;  $LysM^{TLR4Flox}$  n=6). Coverslips were stained with DAPI (405) and CD68 (568) and were imaged at 40x. FITC microbeads have inherent fluorescence on the 488 channel. B) Quantification of FITC microbead phagocytosis by cultured macrophages. The numerical average across 3 technical replicates per animal is represented in the graph. Data were analyzed using a 3-way ANOVA and Sidak's *post-hoc* comparisons. \* =  $p < 0.05$ , \*\* =  $p < 0.005$ , \*\*\* =  $p < 0.0005$ , \*\*\*\* =  $p < 0.00005$ .

### **Immune Cell Infiltration and Neuronal Injury after Paclitaxel Treatment in the DRG is Mediated by TLR4 Activation on Male Macrophages.**

It is well known that first-order pain processing occurs within the DRG by nociceptive neurons receiving sensory input from afferent fibers and modulatory signals from peripheral immune cells (Krames, 2015). Paclitaxel treatment has been shown to induce a neuroinflammatory phenotype in the DRG of human patients and in animal models (Akin et al., 2021; Li et al., 2021). We have previously shown, along with others, that a dose of 16 mg/kg of paclitaxel is sufficient to induce upregulation of ATF3 in the DRG of these mice between 2 and 10 days after initial dosing (Agalave et al., 2021; Peters et al., 2007). This upregulation of ATF3 may be interpreted as a biomarker for neuronal injury and is often associated with reprogramming of neuronal and immune phenotypes, indicating bi-directional communication between the nervous and immune systems in the periphery (Renthal et al., 2020; Tsujino et al., 2000). To better understand how modulatory signals from immune cells affect neuronal injury in the DRG we isolated lumbar DRGs from LysM<sup>TLR4flox</sup> animals 10 days after paclitaxel treatment and performed immunohistochemical analyses to measure the upregulation of ATF3 in neurons and CD68 positive macrophages (Figure 4.4A & B). We found that the number of ATF3 positive neurons was significantly increased in the

DRG of male TLR4<sup>Flox</sup> mice treated with paclitaxel. Interestingly, male LysM<sup>TLR4Flox</sup> mice treated with paclitaxel had significantly reduced ATF3 positive neurons in the DRG as compared to male TLR4<sup>Flox</sup> mice. These effects were not recapitulated in females of either genotype, indicating a sex- and genotype-dependent effect where TLR4 activation on macrophages by paclitaxel administration facilitates upregulation of a neuroinflammatory phenotype only in males (Figure 4.4C, Table 4.4). Moreover, analysis of CD68 positive macrophages in the DRG after paclitaxel treatment reveals significant sex-, treatment- and genotype-dependent effects. Both male and female TLR4<sup>Flox</sup> mice treated with paclitaxel have significantly increased expression of CD68 positive macrophages in the DRG. Intriguingly, paclitaxel treatment increased expression of CD68 positive macrophages in the DRG significantly more in males than in females. Lastly, removal of TLR4 from macrophages in the LysM<sup>TLR4Flox</sup> male mice prevents the paclitaxel-dependent upregulation of CD68 positive macrophages in the DRG. These findings are also not recapitulated in females (Figure 4.4D, Table 4.4). These data show that paclitaxel may facilitate neuroinflammation and injury through TLR4 signaling on macrophages in males, but not females. This is indicative of a sex- and cell-specific difference in the mechanisms behind CIPN development.

**Figure 4.4. Infiltration of macrophages and incidence of neuronal injury in the DRG after paclitaxel treatment.** **A**) Representative images from male vehicle (n=3) and paclitaxel (n=3) treated TLR4<sup>Fllox</sup> and male vehicle (n=3) and paclitaxel (n=4) treated LysM<sup>TLR4Fllox</sup> mice. Sections were stained with DAPI (blue), CD68 (green), and ATF3 (red) and imaged at 20x. **B**) Representative images from female vehicle (n=3) and paclitaxel (n=4) treated TLR4<sup>Fllox</sup> and female vehicle (n=3) and paclitaxel (n=3) treated LysM<sup>TLR4Fllox</sup> mice. Sections were stained with DAPI (blue), CD68 (green), and ATF3 (red) and imaged at 20x. **C**) Quantification of ATF3 positive neurons in the DRG. Data are expressed as the average of 2 technical replicates per animal. **D**) Quantification of CD68 positive macrophages in the DRG. Data are expressed as the average of 2 technical replicates per animal and normalized by the area measured in millimeters<sup>2</sup>. ### **Paclitaxel Treatment Reduces Intraepidermal Nerve Fiber Density in Both Sexes.**

Paclitaxel treatment has been previously shown to reduce IENF density in males (Boyette-Davis et al., 2011). We sought to further investigate this by assessing the potential for sex differences in cell specific TLR4 signaling. To test our hypothesis, we utilized our genetic model, LysM<sup>TLR4Flox</sup>, where we remove the ability for paclitaxel to act on TLR4 expressed by macrophages and monocytes. We then isolated hind limb skin 10 days after paclitaxel treatment and performed immunohistochemical analyses to measure the density of IENFs crossing the basement membrane in the paw (Figure 4.5A & B). Our initial findings recapitulate data shown in the previously mentioned studies, where paclitaxel treatment significantly reduces IENF density in the paw skin of male TLR4<sup>Flox</sup> mice (Boyette-Davis et al., 2011). We also found that paclitaxel treatment reduces IENF density in the paw of female mice—an entirely novel finding. Interestingly, we demonstrate that reduction of IENF density in male mice is mediated by TLR4 signaling on macrophages. Male LysM<sup>TLR4Flox</sup> mice treated with paclitaxel exhibit no significant change from vehicle counterparts, however; these effects are not recapitulated in female LysM<sup>TLR4Flox</sup> mice

(Figure 4.5C, Table 4.5). We believe these data indicate a sex- and cell-specific difference in TLR4 signaling, meaning that males utilize TLR4 signaling on macrophages to facilitate inflammation in the DRG and paw skin. Conversely, paclitaxel acts on a different receptor and cell type to drive the effects we see in wild type females. Lastly, we observed a robust positive correlation between ATF3 expression in DRG nociceptors and CD68+ macrophages in a treatment, sex, genotype dependent manner. Moreover, these variables were also inversely correlated with IENF density, indicating that an increase in neuronal injury markers and macrophage infiltration facilitates IENF retraction in the paw (Figure 4.5D). These effects are attenuated in males lacking macrophage TLR4 but are not recapitulated in females.

**Figure 4.5. Intraepidermal nerve fiber density in the hind paw skin after paclitaxel treatment.** **A)** Representative images from male vehicle (n=3) and paclitaxel (n=3) treated TLR4<sup>Fllox</sup> and male vehicle (n=3) and paclitaxel (n=4) treated LysM<sup>TLR4Fllox</sup> mice. ## DISCUSSION

Our study was designed and powered with the intent to uncover the sex- and cell-specific contributions of macrophage TLR4 signaling in response to paclitaxel-induced peripheral neuropathy. Using our murine genetic tool, LysM<sup>TLR4Flox</sup>, we discovered that the development of mechanical hypersensitivity during CIPN is mediated by signaling processes of TLR4 activation on male macrophages but these findings were not recapitulated in female mice. In addition, we found that inflammatory polarization and antigen presentation in macrophages after paclitaxel treatment is mediated by TLR4 activation only in males. Moreover, a TLR4 mediated increase in

phagocytic activity of macrophages after paclitaxel treatment is exclusive to males. Lastly, retraction of IENFs in the paw skin after paclitaxel treatment occurs in both sexes, but only male mice lacking TLR4 on their macrophages are protected against this.

In line with our previously published work and other literature, both male and female mice develop mechanical and thermal hypersensitivity following paclitaxel administration (Agalave et al., 2021; Hwang et al., 2012; Illias et al., 2022). However, our results showed a potent protective effect where conditional knockout of TLR4 from peripheral macrophages attenuated mechanical but not cold hypersensitivity development after paclitaxel treatment. Moreover, the observed behavioral differences were sex dependent. This led us to believe that macrophage specific activation of TLR4 by paclitaxel facilitates inflammatory mechanisms in males which drives neuropathic pain development. For example, whole-body deletion of TLR4, MyD88 and TRIF prevents CIPN development in both sexes (Woller et al., 2015). Also, infiltration of monocytes in the DRG of male rats following paclitaxel is shown to mediate mechanical hypersensitivity. Depletion of peripheral macrophages using clodronate-filled liposomes reverses the paclitaxel-induced mechanical hypersensitivity and decreases inflammatory cytokine expression (Zhang et al., 2016). While these studies provide clear evidence that TLR4 is necessary for CIPN, our results suggest that sex differences in the macrophage response to paclitaxel underlies this phenotype. These results raised several questions that formed the basis of follow-up experiments throughout this study.

It has previously been shown that paclitaxel treatment facilitates macrophage upregulation and recruitment to the DRG (Jimenez-Andrade et al., 2006; Zhang et al., 2016). Further investigation revealed that these effects were mediated by TLR4 signaling, as intrathecal administration of LPS-RS, a TLR4 antagonist, reversed the paclitaxel-induced upregulation of DRG macrophages in males (Li et al., 2014). While these studies provide ample evidence that connects TLR4 signaling to the macrophage response during CIPN, they raise important questions about the implications of macrophage TLR4 and its role in neuroinflammation within the peripheral nervous system. Interestingly, novel data suggest that activation of TLR4 can initiate macrophage infiltration through upregulation of cluster of differentiation 68 (CD68) and promote polarization towards a pro-inflammatory, or M1 phenotype (Shao et al., 2019; Wanderley et al., 2018). A critical component missing from these studies is the consideration of sex as a variable. We, among many others, have shown that both immune and neuronal cells have sexually divergent mechanisms that regulate pain (Agalave et al., 2021; Mogil, 2020; Szabo-Pardi et al., 2021). Specifically, female macrophages adopt a more anti-inflammatory, or M2, phenotype in response to infection and tissue injury (Keselman et al., 2017; Li et al., 2009). The intricate relationship these cells have with DRG nociceptors dictate changes in homeostatic balance, and dysregulation of feedback systems lead to rampant inflammation and maladaptive neuronal plasticity (Szabo-Pardi, 2021). As such, we cannot assume that downstream outcomes are similar between males and females. In a previous study, we had shown that 10 days after paclitaxel administration ATF3 expression is induced in DRG neurons (Agalave et al., 2021). These data indicate a stressed neuronal phenotype in response to paclitaxel, in both sexes. Unclear, however, was whether paclitaxel acts directly on nociceptors through TLR4, an alternative mechanism, or if bidirectional communication between infiltrated

macrophages and nociceptors exacerbates the injured neuronal phenotype. Thus, we designed an experiment to assess how macrophage activation by TLR4 in response to paclitaxel alters recruitment to the DRG, and how this affects neuronal injury in a sex-dependent manner. Our data suggests that removal of TLR4 from macrophages reduces their magnitude of infiltration in the DRGs, as well as upregulation of neuronal ATF3, in males but not females. Moreover, we demonstrate that direct activation of cultured macrophages by paclitaxel only induces elevated phagocytic behavior in males through TLR4-dependent mechanisms. Thus, we believe inflammatory cytokine signaling from TLR4 activation on macrophages induces neuronal ATF3 upregulation in males, however; females rely on a direct neuronal mechanism of cellular injury. This may be due, in part, to the ability of paclitaxel to interact with, and change the intrinsic excitability of transient receptor potential ankyrin 1 (TRPA1) channels on nociceptive sensory neurons (Zhang & Dougherty, 2014). Opening of TRPA1 channels can modulate action potentials during neuronal activation, and increasing excitability works to amplify afferent signals from nociceptive and sensory nerve fibers in the skin. Persistent signals from these fibers can activate intracellular machinery that leads to neuronal plasticity underlying chronic pain (Alles & Smith, 2018).

Loss of IENFs is a ubiquitous characteristic of neuropathic pain conditions. Decreases in IENF density are often correlated with neuropathy and neuronal hyperexcitability (Cheng et al., 2015). Administration of paclitaxel has been previously shown to reduce IENF density in the paw skin in males, which is often predictive of CIPN development (Boyette-Davis et al., 2011). Since then, many advances have been made in the field providing additional clarity as to the mechanisms that

regulate IENF loss. Specifically, DRG macrophages have been proven to facilitate IENF loss through rampant inflammation. Interestingly, blocking the actions of TLR4 with LPS-RS in the spinal cord prevents the loss of IENFs after paclitaxel treatment (Zhang et al., 2016). While this information provides valuable insights as to the role of glia and immune cells in CIPN, the results prove difficult to interpret since chemotactic signals in the periphery, such as C-C motif chemokine ligand 2 (CCL2), arise from sensory neurons in the DRG, as opposed to the spinal cord. However, ablation of peripheral macrophages using minocycline or clodronate-filled liposomes yields similar effects (Liu et al., 2010). The direct mechanisms involved in IENF loss are still poorly understood, however; expression of inflammatory cytokines has been shown to be robustly correlated with IENF loss (Wang et al., 2012). Exposure to chemotherapeutics increases levels of inflammatory cytokines such as tumor necrosis factor- $\alpha$  (TNF $\alpha$ ), interleukin-1 $\beta$  (IL-1 $\beta$ ), and interleukin-6 (IL-6), all of which are implicated in neuroinflammation and upregulation of cellular injury markers like ATF3 (Zaks-Zilberman et al., 2001). Many of these cytokines are produced as a result of nuclear factor kappa B (NF- $\kappa$ B) phosphorylation and nuclear localization, which is directly downstream of TLR4 activation by paclitaxel. Nevertheless, we believe it to be necessary to demonstrate the direct effects of TLR4 activation on peripheral macrophages to accurately assess their role in paclitaxel-induced neuropathy and IENF retraction. Our data suggests that removal of TLR4 from macrophages prevents the paclitaxel-induced loss of IENFs in the paw of males. Importantly, female IENF density is unaffected by removal of macrophage TLR4. Moreover, we demonstrate a strong positive correlation between CD68 and ATF3 expression in the DRG after paclitaxel treatment. This corroborates data previously published by our group, and others, that suggests DRG macrophages drive inflammation and neuronal plasticity during CIPN

(Agalave et al., 2021; Huang et al., 2014; Zhang et al., 2016). Interestingly, IENF density possesses a robust inverse correlation with these two markers and is modulated by macrophage TLR4 expression in males only. Therefore, we believe that preservation of IENFs by reducing macrophage TLR4 signaling in males may contribute to the reversal of mechanical hypersensitivity induced by paclitaxel. It is likely that one of the mechanisms by which this occurs is through mitochondrial dysfunction in DRG neurons, where paclitaxel-mediated dysregulation of mitochondrial transport and accumulation in axons is compounded by the inability of macrophages to shift towards an anti-inflammatory phenotype (Krukowski et al., 2015; Wanderley et al., 2018). Alternatively, it is possible that females utilize a direct method of nociceptor activation through TLR4, or an alternative mechanism, as it has been shown that paclitaxel increases expression of voltage-gated T-type calcium channels (Cav3.2) in the DRG which is linked to behavioral nociceptive phenotypes (Li et al., 2017). This, coupled with previously mentioned studies that indicate paclitaxel may also act through TRPA1 sensitization, provides a clear direction for future studies investing female-specific mechanisms of CIPN.

Despite the limitations, our study reveals novel insights involving the sex- and cell-specific mechanisms of paclitaxel-induced peripheral neuropathy, which may open new avenues of neuroimmune research and highlight novel treatment strategies. Overall, our data suggest that macrophages mediate neuroimmune interactions through activation of TLR4 by paclitaxel treatment in males, but not in females. While we observed macrophage TLR4-dependent changes in behavioral phenotypes and cellular physiology after paclitaxel treatment in males, females still exhibit the majority of treatment-induced effects in the absence of TLR4. This suggests that the mechanisms and cell types involved in engendering the nociceptive behavioral phenotypes,

neuronal injury and IENF retraction differ between sex. While our study begins to unravel the complex mechanisms behind sex differences in CIPN, more work is necessary to fully elucidate female-specific pathways.

## **ABSTRACT**

Recent studies have brought to light the necessity to discern sex-specific differences in various pain states and different cell-types that mediate these differences. These studies have uncovered the role of neuroimmune interactions to mediate pain states in a sex-specific fashion. While investigating immune function in pain development, we discovered that females utilize immune components of sensory neurons to mediate neuropathic pain development. We utilized two novel transgenic mouse models that either restore expression of toll-like receptor (TLR) 4 in Nav1.8 nociceptors on a TLR4-null background (TLR4<sup>LoxTB</sup>) or remove TLR4 specifically from Nav1.8 nociceptors (TLR4<sup>fl/fl</sup>). After spared nerve injury (SNI), a model of neuropathic injury, we observed a robust female-specific onset of mechanical hypersensitivity in our transgenic animals. Female Nav1.8-TLR4<sup>fl/fl</sup> knockout animals were less mechanically sensitive than *cre*-negative TLR4<sup>fl/fl</sup> littermates. Conversely, female Nav1.8-TLR4<sup>LoxTB</sup> reactivated animals were as mechanically sensitive as their wild-type counterparts. These sex and cell-specific effects were not recapitulated in male animals of either strain. Additionally, we find the danger associated molecular pattern, high mobility group box-1 (HGMB1), a potent TLR4 agonist, localization and ATF3 expression in females is dependent on TLR4 expression in dorsal root ganglia (DRG) populations following SNI. These experiments provide novel evidence toward sensory neuron specific modulation of pain in a sex-dependent manner.

## **INTRODUCTION**

The CDC lists chronic pain as a leading cause of long-term disability, with current treatments remaining ineffective (Dahlhamer et al., 2018). Grim side effects have tallied over 600,000 opioid-

related deaths, with 64% of these cases linked to chronic pain patients since 2010 (Seth et al., 2018). These issues become more complex with females being more susceptible to certain forms of chronic pain (Joseph et al., 2003). Neuropathic pain results from disease or trauma to the nervous system, with injury-induced neuropathic pain estimated to occur in 20–50% of patients following routine operations (Kehlet, 2006). Sufferers often report a significantly reduced quality of life, and the prevalence of chronic pain continues to rise as the number of effective therapeutics remain limited (McDermott et al., 2006). Recent literature highlighting sexual dimorphisms in the onset and chronicity of pain states have begun to alter the way researchers and clinicians approach mechanisms in pain and potential therapeutics. Therefore, a dire need exists to bolster research efforts to identify crucial therapeutic time windows as well as novel and effective alternatives for the treatment and abatement of chronic pain. Here we hope to identify early time-points in the development of neuropathic pain that could represent a viable therapeutic window.

Toll-like receptors (TLRs) are pattern recognition receptors (PRRs) that initiate responses to infection and tissue injury that lead to inflammation and nocifensive behaviors (Hanamsagar et al., 2012; Nicotra et al., 2012; Xiang et al., 2015). TLR4 plays a pivotal role in chronic pain through the activation of pro-inflammatory cytokine production in non-neuronal cells. Pro-inflammatory mediators have been shown to directly sensitize neurons in the dorsal root ganglia (DRG) and exacerbate maladaptive plasticity (Ma et al., 2006). The dynamics of TLR4-mediated activation via microglia is well established where pharmacological inhibition of spinal TLR4 attenuates mechanical hypersensitivity in male, but not female mice (Sorge, 2011; Woller et al., 2016). Moreover, the role for T-cells regulating development of neuropathic pain in females has been

alluded to, however, recent evidence leads us to believe that nociceptive sensory neurons are the primary facilitators of chronic pain etiology (Lopes, 2017). Differential expression of genes involved in nociceptive pathways have been identified with females expressing upregulated genetic markers that correlate with increased inflammation, synaptic transmission, and extracellular matrix (ECM) reorganization (Mecklenburg et al., 2020; Wangzhou et al., 2021).

In the periphery, direct TLR4 stimulation is involved in dental pain via sensitization of trigeminal ganglion neurons (Diogenes et al., 2011), while TLR4 in dorsal root ganglia (DRG) cultures are implicated in chemotherapy-induced neuropathy (Li, Adamek, et al., 2015). Recent studies suggest that TLR4 on peripheral monocytes may play a role in female-specific nociceptive states (Huck et al., 2021), while others refute this claim (Peng, 2016; Yu, 2020). Due to its expression pattern in immune, mesenchymal, and neuronal cell populations, peripheral TLR4 signaling remains an elusive topic and important in both sexes. Importantly, the sex-specific role of TLR4 signaling in DRG neurons is unclear (Allette et al., 2014; Feldman et al., 2012; Hutchinson et al., 2008; Rudjito, 2020). In this study, we ask how endogenous TLR4 activation on peripheral nociceptors mediates the development of neuropathic pain.

Tissue injury upregulates danger-associated molecular patterns (DAMPs) (Man et al., 2015; Wan et al., 2016). High-mobility group box 1 (HMGB1) is a DAMP capable of initiating inflammatory cascades via TLR4 (Yamasoba et al., 2016). HMGB1 is a nuclear-bound redox sensitive cytokine, that is released from the cell upon activation, during tissue damage and changes to oxidative states; disulfide HMGB1 (dsHMGB1), is the predominant species that has affinity for TLR4 (Agalave &

Svensson, 2015; Yamasoba et al., 2016). Intrathecal administration of HMGB1 has been shown to produce robust mechanical allodynia (Agalave, 2020; O'Connor et al., 2003). Elevated levels of circulating HMGB1 promote activation and priming states of immune cells; however, its action on neurons that express TLR4 to elicit pain behavior has not been assessed (Bestall et al., 2018). The notion of neuronal TLR signaling remains contentious as emerging evidence suggests DRG macrophages are involved in communication with sensory neurons following nerve injury in both sexes (Yu et al., 2020). Interestingly, this does not relegate the fact that sensory neurons are activated and directly interact with immune cells (reverse communication). While the magnitude of neuropathic pain may not differ between sexes, the mechanisms which drive its development are clearly different. The timing and mode of communication between immune cells and neurons may help elucidate the mechanisms by which males and females differ.

Utilizing recently developed and validated transgenic models, we were able to specifically remove or reactivate TLR4 on Nav1.8<sup>+</sup> nociceptors in a cre dependent fashion (Jia et al., 2021; Jia et al., 2014). We identified a distinct neuronal-mediated pathway in female mice which contributes to the early onset of peripheral nerve injury-induced mechanical hypersensitivity in addition to uncovering a direct mechanism of neuronal sensitization. We demonstrated that TLR4, expressed specifically on Nav1.8<sup>+</sup> peripheral nociceptors, is responsible for mechanical hypersensitivity during the onset of peripheral nerve injury in female, but not male mice. Additionally, HMGB1 localization and autocrine signaling via these nociceptors, as well as paracrine action on large diameter sensory neurons in the DRG, contribute to pain sensitization in female mice. We believe TLR4 activation on Nav1.8<sup>+</sup> nociceptors is one mechanism of pain sensitization unique to females.

## MATERIALS AND METHODS

### Animals

All animal experiments were carried out in accordance with protocols approved by the Institutional Animal Care and Use Committee of the University of Texas at Dallas. Mice were housed (4–5 per cage) in a temperature-controlled facility and maintained on a 12-hour light/dark cycle (lights on: 7am/ lights off 7 pm). Mice had *ad-libitum* access to food and water and were eight to twelve-weeks-old during the experiments (male, 25–30 g; female 20–25 g). Transgenic mice expressing Cre recombinase under control of the *Scn10a* (*Nav1.8*) promoter were obtained initially from Professor John Wood (University College London), but are commercially available from Ifrafrontier (EMMA ID: 04582). Characterization of these mice showed that heterozygous cre animals have no pain phenotype and normal electrophysiological properties (Stirling et al., 2005). Genetically modified TLR4 floxed animals (has loxP sites flanking exon 2 and 3;  $TLR4^{fl/fl}$ ) (Jia et al., 2014) and TLR4 null-reactivable animals (has a transcriptional blocker inserted into the TLR4 gene in between exon 2 and 3;  $TLR4^{LoxTB}$ ) (Jia et al., 2021) were a gift from Joel K. Elmquist, (UT Southwestern Medical Center) were bred with  $Nav1.8^{cre}$  animals in-house ( $Nav1.8^{cre} \times TLR4^{fl/fl}$ ,  $TLR4^{fl/fl}$ ,  $Nav1.8^{cre} \times TLR4^{LoxTB}$ ,  $TLR4^{LoxTB}$ ) and used for all behavioral and biochemical assays (Jia et al., 2021; Jia et al., 2014). All cell-specific knockout ( $Nav1.8^{TLR4^{fl/fl}}$ ) or cell-specific reactivated ( $Nav1.8^{TLR4^{LoxTB}}$ ) mice are heterozygous for the *Nav1.8-cre* ( $Nav1.8^{cre}$ ) and are homozygous for the  $TLR4^{fl/fl}$  or  $TLR4^{LoxTB}$  gene, respectively. Phenotypically normal littermates lack  $Nav1.8^{cre}$  and are homozygous for the  $TLR4^{fl/fl}$  gene. Whole-body null or knockout mice ( $TLR4^{TB/TB}$ ) lack  $Nav1.8^{cre}$  and are homozygous for the  $TLR4^{LoxTB}$  gene. We purchased  $ROSA26^{LSLtdtomato}$  (tdtomato) animals from Jackson lab (stock no. 007909) and crossed them with

Nav1.8<sup>cre</sup> animals (Nav1.8<sup>tdT+</sup>) for reporter, IHC, and flow cytometry experiments. All strains were backcrossed at least eight generations to maintain C57BL/6J genetic background with animals from Jackson Lab (stock no. 000664). We used in-house bred C57BL/6J animals as wild-type (WT) controls.

### **Surgical procedures**

The spared nerve injury (SNI) model of neuropathic pain was used. Mice were anesthetized under isoflurane anesthesia (1.0–2.5%). The ipsilateral thigh was shaved and cleaned with betadine (Dynarex, 1425) and 70% ethanol (Decon Labs, 2701). The skin and muscle of the left thigh were incised with a #11 scalpel blade (Thermo, 22–079-691) and the sciatic nerve along with its three branches (common peroneal, tibial, and sural) was exposed. A tight ligature using a 5–0 silk suture (VWR, MV-682) was placed around the proximal tibial and common peroneal branches, after which the nerve distal to the ligature was transected, taking care to not stretch or damage the sural nerve (Decosterd, 2000). Sham surgeries were done identically to the SNI surgery; however, no portion of the sciatic nerve was ligated or transected. The skin was closed using an auto clip (Fine Science Tools, 12022-09) and mice were then given a subcutaneous injection of 5 mg/mL Gentamicin (Sigma, G1272) as a preventative antibiotic and returned to their home cages to recover (Decosterd, 2000). Mice were monitored daily for the duration of the experiment. Mechanical hypersensitivity and cold allodynia were then assessed on postoperative days 1, 3, 5 and 7. Baseline values were taken 24 h prior to surgery.

## **Behavioral testing**

To measure mechanical hypersensitivity, mice were individually placed on an elevated wire grid inside acrylic behavior racks and allowed to habituate for approximately 2 h. The ipsilateral hind paw was then stimulated with von Frey filaments (Stoelting, 58011) using the up-down experimental paradigm (Chaplan, 1994). To assess cold allodynia in our SNI model, mice were individually placed on the same elevated wire grid and behavior racks and allowed to habituate for approximately 2 h before testing. Approximately 100  $\mu$ L of biology grade acetone (Fisher, AI6P-4) was then applied to the ipsilateral hind paw using a 1 mL syringe (VWR, 309659) attached to a 25 G needle (VWR, 305125). Latency of behavioral response over a 60 s period was measured (Yoon, 1994). Behavior racks were cleaned with a 1:3 ratio of a plant-based deodorant-free cleaner (Seventh Generation<sup>TM</sup>, 22719BK-5) to eliminate odor cues between each reading, baseline, and experiment. Baseline values were taken 24 h prior to performing surgery. Mechanical hypersensitivity and cold allodynia were then measured on postoperative days 1, 3, 5, and 7. Mechanical measures were always taken before thermal. All behavioral testing was done between 10 a.m. and 2:00p.m. All behavior data sets are additionally represented as effect sizes. It is determined by calculating the cumulative difference between the value for each time point and the baseline value (Agalave et al., 2021; Hassler et al., 2020). Behavioral experiments were performed by T.A.S., L.R.B., and M.D.B. Experimenters were blinded to genotype, surgical condition, or both.

## **Immunohistochemistry**

Three days post SNI, mice were anesthetized using 100% isoflurane and were subsequently euthanized via decapitation. Dorsal root ganglia (L3-5) were extracted and post-fixed in 4%

paraformaldehyde made in 1 × phosphate buffered saline (PBS) (Sigma, 158127) for 4 h and then cryoprotected for 48 h in a 30% sucrose (Sigma, S0389) solution made in 1 × (PBS). Frozen tissues (DRGs: 16 μm) were then transversally sectioned on a cryostat and mounted onto SuperFrost Plus (Fisher, 12–544-7) charged microscope slides. Slides were then allowed to dry for 1 h before being placed in the –80° C freezer overnight. Slides were then rehydrated in 1 × PBS for 5 min before being incubated in a blocking/permeabilization solution consisting of: 1 × PBS, 2% heat-inactivated normal goat serum (Sigma, G9023), 1% bovine serum albumin (Sigma, A9576-50ML), 0.1% Triton (Sigma, X100), 0.05% Tween-20 (Sigma, P1379) and 0.05% sodium azide (Ricca Chemical, R7144800). Slides were then incubated overnight at 4° C in a primary antibody cocktail diluted in blocking/permeabilization solution. The following day slides were washed three times for 5 min each in 1 × PBS + 0.05% Tween-20 and incubated for 2 h at room temperature in their respective secondary antibodies diluted in blocking/permeabilization solution. Slides were then washed three times for 5 min each in 1 × PBS + 0.05% Tween-20 and mounted using Prolong gold (Thermo, P36974) mounting media and a 1.5 mm glass coverslip (Thermo, 08–774-384). Slides were stored at 4° C until imaging. Images used for analysis and quantification were taken on a Zeiss Axioobserver 7 epifluorescent Microscope at 20x. Representative images were taken at 20x (ATF3 and tdTomato images) or 40x (HMGB1 images) using an Olympus FluoView 3000 RS confocal microscope. Analysis of images was done using ImageJ Version 1.48 (National Institutes of Health, Bethesda, MD) for Mac OS X (Apple). Immunohistochemistry (IHC) experiments and analyses were performed by T.A.S., and L.R.B. Experimenters were blinded to sex, genotype, and surgical condition. For a complete list of antibodies used refer to Table 1.

## **Flow cytometry**

Flow cytometric analysis of isolated DRGs was performed based on previous protocols with some modifications (Chiu et al., 2014). In brief, ipsilateral and contralateral DRGs (L3-4) were collected in ice cold sterile 1 × DPBS (Hyclone, SH30028). Samples were centrifuged at 400 × g for 3 min. Supernatants were removed and samples were treated with Collagenase A (Sigma, 10103586001) and incubated in a 37 °C water bath for 20 min. Samples were then centrifuged at 400 × g for 3 min. Supernatants were removed and the samples were treated with Collagenase D (Sigma, 1188866001) and a 10% v/v of papain (Roche, 10108014001) in HBSS for another 20 min. Cells were centrifuged at 400 × g and the pellet were resuspended in Enzyme T (Sigma, 10109886001) (soybean trypsin inhibitor made in 1:1 bovine serum albumin and DMEM/F12 media (Thermo, 10565161) supplemented with 10% fetal bovine serum (FBS) (Hyclone, SH30088.03) and 1% pen/strep (Sigma, P4333)) to stop the enzymatic reaction. Digested tissues were triturated using a 1 mL fire-polished Pasteur pipette tip and passed through a 70- $\mu$ m nylon mesh cell strainer (Sigma, CLS431751-50EA), with a subsequent wash using flow buffer (0.5% bovine serum albumin with 0.02% glucose (Sigma, G7528) made in 1 × DPBS). Resultant suspension was centrifuged at 400 × g for 3 min and resuspended in flow blocking buffer (anti-CD16/32 purified antibody diluted in flow buffer) for 20 min to block fc receptors. Samples were incubated with pre-conjugated extracellular flow antibodies (CD45 & TLR4) for 45 min. Samples were then washed with flow buffer, then centrifuged at 400 × g for 3 min and resuspended in a fixation/permeabilization buffer (BD Biosciences, 555028) for 45 min. Samples were then centrifuged at 400 × g for 3 min and were washed twice using the manufacturer provided wash buffer (1 × ). Samples were incubated with pre-conjugated intracellular flow antibodies (NeuN)

for 60 min and washed with DAPI for 5 min. Samples were then centrifuged at  $400 \times g$  for 3 min and were washed twice using wash buffer and were then resuspended in flow buffer. Appropriate compensation controls and isotypes were used for determination and gating. After gating DAPI positive cells (to determine debris), immune cells were identified with gating for CD45 and were further gated to identify expression of TLR4. Neurons were initially identified with gating for NeuN and were further gated to identify expression of TLR4. Stained samples were analyzed using a Special Order (4-laser) Becton-Dickinson Fortessa analyzer (Red Oaks, CA) and data were analyzed using FlowJo and FCS Express software (De Novo Software, Los Angeles, CA). Flow cytometry experiments and analyses were performed by T.A.S., M.E.L., and M.D.B. Experimenters were blinded to genotype and surgical condition. For a complete list of antibodies used refer to Table 1.

### **Statistical analysis**

Prism 8.01 software (GraphPad, San Diego, CA, USA) was utilized to generate all graphs and statistical analysis. Behavioral data was analyzed using repeated measures Two-Way ANOVA with Tukey's *post hoc* tests. Effect size, immunohistochemical, and flow cytometric data were analyzed using Ordinary Two-Way ANOVA with Tukey's *post hoc* tests. All data are represented as the standard error of the mean (SEM). A *p*-value of  $< 0.05$  was used to determine statistical significance. All statistical values and corresponding tests can be found in Table 2, Table 3, Table 4, Table 5, Table 6, and Table 7. All behavioral, immunohistochemical, and flow cytometric experiments and analyses were performed by blinded experimenters.

## RESULTS

**The severity of mechanical hypersensitivity and cold allodynia in a neuropathic pain model is similar between males and females, but protein expression levels in the lumbar DRG are different**

To establish if any sexual dimorphisms exist in the magnitude of pain following neuropathic injury, SNI was performed on both male and female WT mice. No significant differences were found between male and female SNI groups in either mechanical hypersensitivity or cold allodynia (Fig. 5.1A-D, Table 5.2). Emerging evidence suggests that the mechanisms that mediate neuronal sensitization during the early onset of neuropathic pain differ between sexes (Ross et al., 2018;

Tajerian et al., 2015). Myeloid-derived immune cells are strongly implicated in driving the early onset of pain following injury, however; differences between sexes in direct neuronal sensitization in the lumbar DRG are poorly understood (Peng et al., 2016). To test the hypothesis that neuronal injury after SNI is different between males and females we first utilized our Nav1.8<sup>tdT</sup> reporter line to verify colocalization between our Nav1.8 antibody and cre-mediated tdTomato expression in Nav1.8<sup>+</sup> nociceptors. Naïve male and female Nav1.8<sup>tdT</sup> lumbar DRGs (L3-5) were immunoassayed with Nav1.8 and NF200 antibody (Fig. .1E, Table 5.2). They were then assessed for colocalization with tdTomato. We found there to be a high degree of colocalization (75%) between Nav1.8 antibody and tdTomato expression (Fig. 5.1F, Table 5.2). This indicates robust specificity of the Nav1.8 antibody with endogenous expression of tdTomato. Next, we used histochemical markers to identify small (Nav1.8) and large (NF200) diameter nociceptors in the DRG (L3-5) of male and female WT mice. We then examined HMGB1 cytosolic localization and ATF3 expression in these distinct neuronal populations 3 days post SNI (Fig. 5.1G-J, Table 5.2). We discovered a sexual dimorphism where both male and female small diameter nociceptors (Nav1.8<sup>+</sup>) exhibit significantly elevated expression of ATF3 3 days post SNI, but females have significantly more ATF3 expressed as compared to males. (Fig. 5.1K, Table 5.2). Both males and females have significantly increased ATF3 expression in their large diameter sensory neurons (NF200<sup>+</sup>) 3 days post SNI as compared to sham controls (Fig. 5.1L, Table .2). It is evident that these neuronal subpopulations exhibit signs of cellular injury in both males and females after SNI. We then measured cellular localization of HMGB1 in these neuronal subpopulations. Only female WT mice exhibit significantly elevated cytosolic localization of HMGB1 3 days post SNI in their Nav1.8<sup>+</sup> nociceptors as compared to sham controls (Fig. 5.1M, Table 5.2). Additionally, only

female WT mice exhibit significantly elevated cytosolic localization of HMGB1 3 days post SNI in their NF200<sup>+</sup> neurons as compared to sham controls (Fig. 5.1N, Table 5.2). Taken together, our data reveals an inherent sexual dimorphism in both inflammatory signaling and neuronal injury in the context of neuropathic pain. This simple, yet enlightening finding pushed us to further investigate the dichotomy of sex and cell-specific sensitization in the peripheral nervous system.

**Figure 5.1. The magnitude of pain after SNI does not differ between sexes following SNI, however; the mechanisms during its onset at the level of the lumbar (L3-5) DRGs are.** Spared-nerve injury was performed on the left hindlimb of male and female mice. **A**, Hind paw mechanical withdrawal thresholds were measured prior to surgery and on days: 1, 3, 5, and 7 post-surgery in both male and female sham (n = 7) and SNI (n = 7) wild type mice. **B**, Data for males and females combined shown as mechanical effect size. **C**, Hind paw response to application of acetone were measured prior to surgery and on days: 1, 3, 5, and 7 post-surgery in both male and female sham (n = 7) and SNI (n = 7) mice. **D**, Data for males and females combined shown as acetone effect size. **E**, Naïve Na<sub>v</sub>1.8<sup>tdT</sup> female and male lumbar (L3-5) DRGs were immunostained with Na<sub>v</sub>1.8 (green), tdTomato (red) and NF200 (Blue); representative images from n = 4 mice). Scale bar: 50 μm. Magnification: 20x. **F**, Quantification of colocalization between Na<sub>v</sub>1.8, tdTomato and NF200 (n = 4). **G-H** Female and male WT lumbar DRGs (L3-5) were immunostained 3D post SNI with DAPI (teal), Na<sub>v</sub>1.8 (green), ATF3 (red) and NF200 (blue; representative images from n = 4 mice). Scale bar: 50 μm. Magnification: 20x. **K**, Quantification of ATF3 colocalization with

Nav1.8<sup>+</sup> neurons of both sexes 3 days after SNI (n = 4 per group). **L**, Quantification of ATF3 colocalization with NF200<sup>+</sup> neurons of both sexes 3 days after SNI (n = 4 per group). **I-J**, Female, and male WT lumbar DRGs (L3-5) were immunostained 3D post SNI with DAPI (teal), Nav1.8 (green), HMGB1 (red) and NF200 (blue; representative images from n = 4 mice). White arrows point to an example of nuclear or cytosolic localization of HMGB1. Scale bar: 20  $\mu$ m. Magnification: 40x. **M**, Quantification of HMGB1 cytosolic localization in Nav1.8<sup>+</sup> neurons of both sexes 3 days after SNI (n = 4 per group). **N**, Quantification of HMGB1 cytosolic localization in NF200<sup>+</sup> neurons of both sexes 3 days after SNI (n = 4 per group). \**p* < 0.05; \*\**p* < 0.01; \*\*\*\**p* < 0.0001. BL = Baseline. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

### Sensory neuron and immune cell expression of TLR4

To investigate baseline and surgery-induced levels of TLR4 on DRG cell populations, ipsilateral and contralateral DRGs (L3-L5) were isolated from males and females 3 days post SNI (Chiu et al., 2014). Moreover, we verified protein expression of our null-re-expression animals when we added whole-body null (TLR4<sup>LoxTB</sup>) and cell-specific re-expression (Nav1.8<sup>TLR4LoxTB</sup>) groups to the study. Neuronal (NeuN<sup>+</sup>) and immune cell (CD45<sup>+</sup>) populations were identified and assessed for TLR4 at various stages and genotypes (Fig. 5.2A). We determined that there were no significant

sex or surgery-induced differences in TLR4 protein expression patterns in DRG neurons in ipsilateral DRGs, compared to contralateral DRGs, with roughly 30% of the neurons expressing TLR4 in males and females (Fig. 5.2B & 2C; Table 5.3). We saw that our whole-body null animals expressed minimum amounts of TLR4 across the neuronal populations, as expected (Fig. 5.2B & 2C; Table 5.3). Oppositely, we observed a male-driven sex-dependent upregulation of ipsilateral TLR4 expression in CD45<sup>+</sup> immune cells 3 days post SNI (Fig. 5.2E; Table 5.3), but no female differences. This data juxtaposes recent findings of no sex-differences in DRG immune cells after neuropathic injury (Yu et al., 2020). Apparently, it is imperative to understand not only the cell population amount, but the expression pattern of those cells in the DRG.

**Figure 5.2.** There are no basal or surgery-induced sex differences in TLR4 expression in sensory neurons and a surgery-induced upregulation of TLR4 in DRG immune cells 3D post SNI. *A*, Lumbar DRGs (L3-5) were enzymatically dissociated, stained with TLR4, NeuN, and DAPI and subjected to flow cytometry. After gating on both neurons and immune cells based on forward and side scatter, NeuN<sup>+</sup> and CD45<sup>+</sup> cells were further gated to TLR4<sup>+</sup> populations. *B*, NeuN<sup>+</sup>/TLR4<sup>+</sup> cells in control (contra) and surgerized DRGs (ipsi) 3D post SNI in males. *C*, NeuN<sup>+</sup>/TLR4<sup>+</sup> cells in control (contra) and surgerized DRGs (ipsi) 3D post SNI in females. *D*, Combined male and female data; ratio of ipsilateral-to-contralateral NeuN<sup>+</sup>/TLR4<sup>+</sup> DRG cells 3D post SNI. *E*, CD45<sup>+</sup>/TLR4<sup>+</sup> cells in control (contra) and surgerized DRGs (ipsi) 3D post SNI in males. *F*, CD45<sup>+</sup>/TLR4<sup>+</sup> cells in control (contra) and surgerized DRGs (ipsi) 3D post SNI in females. *G*, Combined male and female data; ratio of ipsilateral-to-contralateral CD45<sup>+</sup>/TLR4<sup>+</sup> DRG cells 3D post SNI. Asterisks on the bar graphs indicate significant differences between the groups. \* $p < 0.05$ ; \*\* $p < 0.01$ ; \*\*\* $p < 0.001$ , (n = 3–4).

### **Sensory neuron TLR4 is necessary during the onset of neuropathic mechanical hypersensitivity in female mice**

Investigating the cell-specific implications of TLR4 activation in behavioral pain phenotypes is necessary to understand the biological relevance of cell-molecule interactions. Danger signals are released by both neuronal and non-neuronal cells in response to tissue injury, where neuronally expressed TLR4 allows for rapid detection of these proteins (Liu et al., 2014). Here, we asked if there are sex differences in the response to neuropathic tissue injury by neuronally expressed TLR4. To test this, we used transgenic male and female mice that lack TLR4 on their Nav1.8<sup>+</sup> nociceptors combined with a spared nerve injury (SNI) model of peripheral neuropathic injury (Fig. 5.3A). Genotypes for Nav1.8<sup>TLR4fl/fl</sup> mice are confirmed using polymerase chain reaction (PCR) and gel electrophoresis (Fig. 5.3B, C). We assessed the onset of neuropathic pain by measuring mechanical hypersensitivity and cold allodynia and our data reveals robust sex and genotype-dependent behavioral effects (Mecklenburg et al., 2020). Our data demonstrates the role of TLR4 in nociceptors and their female-specific role in regulating neuropathic pain development. Male Nav1.8<sup>TLR4fl/fl</sup> mice exhibit similar mechanical withdrawal thresholds to their TLR4<sup>fl/fl</sup> littermates after SNI (Fig. 5.3D, Table 5.4). Female Nav1.8<sup>TLR4fl/fl</sup> mice exhibit reduced mechanical withdrawal thresholds days 1, 3 and 5 after SNI as compared to their TLR4<sup>fl/fl</sup> littermates (Fig. 5.3E, Table 5.4). Sexes are directly compared using effect sizes (Fig. 5.3F, Table 5.4). Interestingly, male but not female mice show reduced cold allodynia on day 3 post-surgery as compared to their TLR4<sup>fl/fl</sup> littermates (Fig. 5.3G-H, Table 5.4). Sexes are directly

compared using effect sizes (Fig. 5.3I, Table 5.4). This demonstrates a distinction in the role of TLR4 in mechanical vs. thermal during neuropathic pain development. It is possible that the mechanisms which mediate cold and mechanical hypersensitivity are sexually dimorphic in nature, and a distinguished subset of transient receptor potential (TRP)<sup>+</sup> sensory neurons in the DRG differ mechanistically between males and females in a neuropathic state, however; this was not the focus of the current study.

**Figure 5.3. Development of neuropathic pain is attenuated in  $Na_v1.8^{TLR4^{fl/fl}}$  female, but not male mice.** Spared-nerve injury was performed on the left hindlimb of male and female mice. **A**, Schematic representing the murine genetic model,  $Na_v1.8^{TLR4^{fl/fl}}$ . **B**, Example PCR, and gel electrophoresis for  $Na_v1.8^{cre}$ . A - indicates homozygous WT mice, a -/+ indicates heterozygous  $Na_v1.8^{cre}$  mice, a +/+ indicates homozygous  $Na_v1.8^{cre}$ . **C**, Example PCR, and gel electrophoresis for  $TLR4^{fl/fl}$ . A - indicates homozygous WT mice, a -/+ indicates heterozygous  $TLR4^{fl/fl}$  mice, a +/+ indicates homozygous  $TLR4^{fl/fl}$  mice. **D-E**, Hind paw mechanical withdrawal thresholds were measured prior to surgery and on days: 1, 3, 5, and 7 post-surgery in both male and female sham (n = 8),  $TLR4^{fl/fl}$  (n = 9),  $Na_v1.8^{TLR4^{fl/fl}}$  (n = 8) mice. **F**, Data for males and females combined shown as mechanical effect size. **G-H**, Hind paw response to application of acetone were measured

prior to surgery and on days: 1, 3, 5, and 7 post-surgery in both male and female sham (n = 8), TLR4<sup>fl/fl</sup> (n = 9) and Nav1.8<sup>TLR4fl/fl</sup> (n = 8) mice. **I**, Data for males and females combined shown as acetone effect size. Asterisks on the line graphs indicate significant differences between the Nav1.8<sup>TLR4fl/fl</sup> and TLR4<sup>fl/fl</sup> groups. \**p* < 0.05; \*\**p* < 0.01; \*\*\**p* < 0.001; \*\*\*\**p* < 0.0001. ### **Sensory neuron TLR4 is sufficient during the onset of neuropathic mechanical hypersensitivity in female mice**

Whole body TLR4 has been shown to influence recovery from a non-terminal neuropathic injury (Stokes et al., 2013). Moreover, TLR4 knockout mice have reduced mechanical and thermal hypersensitivity in response to neuropathic injury (Piao et al., 2018). It is still unclear what specific populations of cells that express TLR4 contribute to these behavioral effects. To investigate the direct action of TLR4 on peripheral sensory neurons, we utilized Nav1.8<sup>TLR4LoxTB</sup> mice combined with an SNI model of neuropathic pain (Fig. 5.4A). Genotypes for Nav1.8<sup>TLR4LoxTB</sup> mice are confirmed using PCR and gel electrophoresis (Fig. 5.4B, C). Here, we tested the sufficiency of TLR4 expressed only on Nav1.8<sup>+</sup> DRG neurons to produce a neuropathic behavioral pain phenotype similar to wild type mice. Analysis reveals significant genotype-dependent behavioral phenotypes and robust sex differences. Male TLR4<sup>LoxTB</sup> mice show significantly diminished mechanical withdrawal thresholds during days 1, 3 and 5 post-surgery as compared to WT littermates. Interestingly, male Nav1.8<sup>TLR4LoxTB</sup> mice do not recapitulate the severe mechanical hypersensitivity seen in WT littermates on days 1, 3 and 5 post-surgery (Fig. 5.4D, Table 5.5). Female TLR4<sup>LoxTB</sup> mice show significantly diminished mechanical withdrawal thresholds during days 1, 3 and 5 post-surgery as compared to WT littermates, however; only female Nav1.8<sup>TLR4LoxTB</sup> mice recapitulate the severe mechanical hypersensitivity seen in WT littermates on days 1, 3 and 5 post-surgery (Fig. 5.4E, Table 5.5). Sexes are directly compared using effect

sizes (Fig. 5.4F, Table 5.5). Surprisingly, no sex or genotype-dependent effects are seen across time in cold allodynia development (Fig. 5.4G-H, Table 5.5). Sexes are directly compared using effect sizes (Fig. 5.4I, Table 5.5). These data suggest direct activation of neuronally expressed TLR4 by endogenous danger signals released during injury is enough to cause a neuropathic behavioral pain phenotype only in female mice.

**Figure 5.4. Development of neuropathic pain is phenotypically normal in  $Na_v1.8^{TLR4LoxTB}$  female, but not male mice.** Spared-nerve injury was performed on the left hindlimb of male and female mice. **A**, Schematic representing the murine genetic model,  $Na_v1.8^{TLR4LoxTB}$ . **B**, Example PCR, and gel electrophoresis for  $Na_v1.8cre$ . A - indicates homozygous WT mice, a +/- indicates heterozygous  $Na_v1.8cre$  mice, a ++ indicates homozygous  $Na_v1.8cre$ . **C**, Example PCR, and gel electrophoresis for  $TLR4^{LoxTB}$ . A - indicates homozygous WT mice, a +/- indicates heterozygous  $TLR4^{LoxTB}$  mice, a ++ indicates homozygous  $TLR4^{LoxTB}$  mice. **D-E**, Hind paw mechanical withdrawal thresholds were measured prior to surgery and on days: 1, 3, 5, and 7 post-surgery in both male and female sham (n = 12), wild type (n = 4),  $TLR4^{LoxTB}$  (n = 9), **F**, Data for males and females combined shown as mechanical effect size. **G-H**, Hind paw response to application of acetone were measured prior to surgery and on days: 1, 3, 5, and 7 post-surgery in both male and female sham (n = 12), wild type (n = 4),

TLR4<sup>LoxTB</sup> (n = 9), Nav1.8<sup>TLR4LoxTB</sup> (n = 7) mice. **I**, Data for males and females combined shown as acetone effect size. Asterisks on the line graphs indicate significant differences between the Nav1.8<sup>TLR4LoxTB</sup> and TLR4<sup>LoxTB</sup> groups. \**p* < 0.05; \*\**p* < 0.01; \*\*\**p* < 0.001; \*\*\*\**p* < 0.0001. BL = Baseline.

**Table 5.5.** Statistical values corresponding to the data in Figure 5.4.

## **Injury marker, ATF3, in small diameter neurons is upregulated in a sex specific and TLR4 fashion**

To investigate the sexual dimorphisms driving the development of neuropathic pain we used a neuronal marker of injury, ATF3, and assessed colocalization with small diameter nociceptors ( $\text{Nav}1.8^+$ ) and large diameter neurons ( $\text{NF}200^+$ ) (Fig. 5.5A-B, Table 5.6). In female  $\text{Nav}1.8^{\text{TLR}4\text{LoxTB}}$  mice, we show significantly upregulated ATF3 expression in their  $\text{Nav}1.8^+$  DRG neurons 3 days post-SNI as compared to  $\text{TLR}4^{\text{LoxTB}}$  mice. Conversely, in male  $\text{Nav}1.8^{\text{TLR}4\text{LoxTB}}$  mice there is no significant upregulation of ATF3 3 days post-SNI in their  $\text{Nav}1.8^+$  DRG neurons as compared to  $\text{TLR}4^{\text{LoxTB}}$  counterparts. There is, however, a significant upregulation in both male and female WT mice 3 days after SNI as compared to shams (Fig. 5.5C, Table 5.6). This sets a precedent that endogenous TLR4 activation on  $\text{Nav}1.8^+$  nociceptors after nerve injury regulates transcription factors (ATF3) that are important in neuronal injury in female, but not male mice. Both male and female  $\text{Nav}1.8^{\text{TLR}4\text{LoxTB}}$  mice exhibit no significant differences in ATF3 expression after SNI as compared to  $\text{TLR}4^{\text{LoxTB}}$  counterparts in  $\text{NF}200^+$  neurons. There is, however, a significant upregulation in both male and female WT mice 3 days after SNI as compared to shams (Fig. 5.5.D, Table 5.6). This data demonstrates that TLR4 has an important role in regulating neuronal injury after neuropathic injury in both sexes, but the cell types that express TLR4 which are responsible for these effects differ between males and females. This interesting finding led us to investigate the downstream implications of TLR4 activation on these small diameter nociceptors via HMGB1 localization.

**Figure 5.5. ### **TLR4 expression in small diameter neurons mediates HMGB1 translocation from the nucleus to the cytosol of the cell**

We demonstrated the sufficiency of TLR4 to upregulate the injury marker, ATF3, in Nav1.8<sup>+</sup> DRG neurons in female, but not male mice. Now that we have established a significant role for TLR4 in regulating neuronal injury, we further investigated the downstream implication of TLR4 signaling in these populations of small and large diameter DRG neurons. Here, we immunoassayed lumbar DRGs (L3-5) from female and male Nav1.8<sup>TLR4LoxTB</sup>, TLR4<sup>LoxTB</sup>, and WT mice 3 days post-SNI for cellular localization of HMGB1, a DAMP, in both small (Nav1.8<sup>+</sup>) and large (NF200<sup>+</sup>) diameter neurons (Fig. 5.6A, B). We found there to be a trend of increased cytosolic HMGB1 in female Nav1.8<sup>+</sup> DRG neurons of Nav1.8<sup>TLR4LoxTB</sup> mice as compared to TLR4<sup>LoxTB</sup> mice. Interestingly, male Nav1.8<sup>TLR4LoxTB</sup> mice do not show significantly increased cytosolic HMGB1 in their Nav1.8<sup>+</sup> DRG neurons 3 days after SNI as compared to TLR4<sup>LoxTB</sup> mice. These results are recapitulated only in female WT mice, indicating direct activation of TLR4 on Nav1.8<sup>+</sup> DRG neurons through endogenous DAMP signaling is sufficient to induce mobilization of HMGB1 to the cytosol of the cell (Fig. 5.6C, Table 5.7). We find no significant differences between both male and female Nav1.8<sup>TLR4LoxTB</sup> and TLR4<sup>LoxTB</sup> mice regarding cytosolic HMGB1 localization in NF200<sup>+</sup> large diameter DRG neurons 3 days after SNI (Fig. 5.6D, Table 5.7). These highly sex and genotype dependent results indicate that endogenous activation of TLR4 on sensory neurons in the DRG of female mice after neuropathic injury initiates cytosolic mobilization of HMGB1. This, taken together with the upregulation of ATF3 expression in nociceptors indicates females utilize a TLR4-dependent pathway to facilitate pain behaviors during a neuropathic injury.

**Figure 5.6. HMGB1 translocation following neuropathic injury is upregulated in a sex and genotype dependent manner in small diameter nociceptors and is mediated by TLR4.** **A**, Female sham (mixed genotypes), WT, Na<sub>v</sub>1.8<sup>TLR4LoxTB</sup>, and TLR4<sup>LoxTB</sup> lumbar (L3-5) DRGs were immunostained 3D post SNI with DAPI (teal), Na<sub>v</sub>1.8 (green), HGMB1 (red) and NF200 (blue; representative images from n = 4 mice). White arrows point to an example of nuclear or cytosolic localization of HMGB1. **B**, Male sham (mixed genotypes), WT, Na<sub>v</sub>1.8<sup>TLR4LoxTB</sup>, and TLR4<sup>LoxTB</sup> lumbar (L3-5) DRGs were immunostained 3D post SNI with DAPI (teal), Na<sub>v</sub>1.8 (green), HGMB1 (red) and NF200 (blue; representative images from n = 4 mice). White arrows point to an example of nuclear or cytosolic localization of HMGB1. **C**, Quantification of cytosolic localization of HMGB1 in Na<sub>v</sub>1.8<sup>+</sup> neurons of both sexes (n = 4 per group). **D**, Quantification of cytosolic localization of HMGB1 in NF200<sup>+</sup> neurons of both sexes (n = 4 per group). Scale bar: 20 μm. Magnification: 40x. \**p* < 0.05; \*\**p* < 0.01; \*\*\*\**p* < 0.0001. ns = not significant. ## DISCUSSION

In the nociceptive system, bi-directional communication between neuronal and non-neuronal cells is a core mechanism in mediating the response to injury (Iwata, 2017; Szabo-Pardi, 2021). Emerging evidence suggests that both sexes utilize myeloid-derived immune cells in the central and peripheral nervous system to drive cytokine production and subsequent neuronal sensitization (Peng, 2016; Yu et al., 2020). Currently, little is known about direct neuronal response to activation by endogenous DAMP signaling during injury. Here, we report that female mice utilize a specific pathway where direct activation of TLR4 by endogenous danger signals on small diameter nociceptors in the DRG leads to upregulation of stress-induced ATF3 and DAMPs (HMGB1) in the lumbar DRG. Additionally, these molecular changes lead to a delay in the onset of neuropathic pain associated with peripheral nerve injury in a TLR4 dependent manner (Fig. 5.7). Our genetic and histological experiments demonstrate a robust sexual dimorphism wherein peripheral nociceptors expressing TLR4 mediate the early onset of neuropathic mechanical hypersensitivity in female mice, in addition to regulating molecular changes in peripheral nervous tissue. Moreover, TLR4 expression on  $Na_v1.8^+$  DRG neurons is both necessary and sufficient for the behavioral response to neuropathic injury. Use of this genetic model has allowed us to elucidate a novel pathway to neuronal injury in female mice. Our results support the

idea that TLR4 signaling on peripheral nociceptors plays an important role in direct sensitization through the up-regulation of stress-induced transcription factors and DAMPs in these cells. In our view, this identifies a novel mechanism of direct neuronal sensitization in female mice crucial for the early onset of neuropathic pain. This provides novel evidence for the dissection of the sexually dimorphic response to tissue injury (Anwar et al., 2019).

**Figure 5.7. Schematic model indicated that TLR4 expressed on Na<sub>v</sub>.1.8<sup>+</sup> nociceptors in the lumbar DRGs (L3-5) plays an important role in regulating the localization of HMGB1 in response to neuropathic injury in females, but not males.** This is both behaviorally and molecularly significant, as female mice lacking TLR4 expression on their Na<sub>v</sub>.1.8 + nociceptors exhibit reduced mechanical hypersensitivity following SNI. Moreover, re-expression of TLR4 only on these Na<sub>v</sub>.1.8 nociceptors recapitulates a behavioral phenotype similar to that of wild type mice. This effect is not present in male mice of either genotype.

Women are found to have a higher incidence of neuropathic pain as compared to males, in addition to lowered efficacy of common therapeutics (DiBonaventura et al., 2017). As such, there exists a need to understand the core mechanisms that differentiate male and female nociceptive circuitry. Compared with the well-documented behavioral phenotypes seen after SNI, we show that male and female wild type mice exhibit no differences in the magnitude of both mechanical hypersensitivity and cold allodynia (Bravo-Caparrós et al., 2019; Sorge, 2015). Interestingly, evidence suggests a fundamental disconnect between the mechanisms involved in the onset of neuropathic pain (Mogil, 2020). For example, male mice lacking chemokine receptor 1 (CX3CR1) expressing immune cells exhibit delayed development of been shown that neuronally expressed NOD-like receptor protein 3 (NLRP3) inflammasome has sex specific effects in pain, where females are dependent on NLRP3 in sensory neurons to facilitate mechanical hypersensitivity (Cowie et al., 2019). NLRP3 inflammasome activation is enhanced via intracellular cascades initiated through TLR4 activation (Bauernfeind et al., 2009). Importantly, inflammasome activation in tissue injury increases production of IL-1 $\beta$ , which plays a prominent role in pain, specifically mechanical hypersensitivity (Chen, 2015). Sensory neurons express large amounts of interleukin (IL) –1 $\beta$  receptor, which leads us to believe that autocrine signaling through the TLR4 and NLRP3 pathways in sensory neurons presents a point of sexually divergent mechanisms of pain sensitization.

In response to this, we sought to characterize endogenous DAMP signaling and chose to focus on HMGB1, specifically, as it has been implicated by numerous studies in chronic pain development (Campana et al., 2009; O'Connor et al., 2003; Zhao et al., 2015). HMGB1 is localized

in the nucleus of cells in homeostasis, however; with adequate stimulation, hyperacetylation of the protein causes translocation to the cytosolic and subsequent release in both neuronal and non-neuronal cells (Lotze & Tracey, 2005). Secreted HMGB1 acts on a variety of receptors, namely the receptor for advanced glycation and end products (RAGE), TLR2, TLR4 and TLR5 all of which are involved in immunomodulation and neuroinflammation (Das et al., 2016; Frasnelli et al., 2015). Interestingly, HMGB1 is capable of upregulating canonical NLRP3 activation, both of which are dependent on the nuclear factor (NF)- $\kappa$ B pathway which is directly linked to TLR4 signaling (Chi et al., 2015). Downstream consequences of neuronally-expressed TLR4 activation are poorly understood, however; evidence does suggest that neurons are able to produce cytokines through its activation (Leow-Dyke et al., 2012). Moreover, it has been demonstrated that activation of TLRs on sensory neurons does promote the production of neuropeptides and chemokines which may facilitate neuronal sensitization (Diogenes et al., 2011). To our surprise, we have identified a robust sexual dimorphism in the lumbar DRG 3 days after SNI. Wild type female mice exhibit elevated cytosolic localization of HMGB1 in Nav1.8 expressing nociceptors. Cytosolic localization of HMGB1 after injury is decreased in both male and female TLR4 knockouts, but only females with TLR4 reactivated in their Nav1.8 neurons see an increase that trends towards a wild type phenotype. Moreover, this same population of peripheral nociceptors in females express higher levels of neuronal injury measured by upregulated ATF3 expression. We demonstrate that this increase in ATF3 expression is linked to TLR4 expression, as both male and female TLR4 knockouts have lower expression of ATF3 after injury. ATF3 has been shown to be a negative regulator of TLR4 activity by dampening the activity of NF- $\kappa$ B. Although co-expression of ATF3 and HMGB1 were not performed, it is a potential that the increase in ATF3 localization within

Nav1.8<sup>+</sup> neurons is due to endogenous TLR4 activation from tissue injury (Kwon et al., 2015; Rao et al., 2015). These data provide evidence that neuronally-expressed HMGB1 is involved in the onset of neuropathic pain in females, however; in future experiments it may be necessary to distinguish specific subsets of nociceptor populations (isolectin b4 (IB4) vs. calcitonin gene related peptide (CGRP)) that express HMGB1 to enhance granularity as to the specific circuitry involved. Nonetheless, this novel finding leads us to believe that females utilize more neuronally-driven mechanisms to facilitate chronic pain development.

To better understand the implications of direct neuronal activation through endogenous TLR4 signaling, we use two recently developed transgenic lines wherein TLR4 is either deleted (Nav1.8<sup>TLR4fl/fl</sup>) or reactivated (Nav1.8<sup>TLR4LoxTB</sup>) constitutively in a cre dependent manner (Jia et al., 2020). Evidence suggests TLR4 plays a major role in regulating the onset of neuropathic mechanical hypersensitivity, but not its persistence (Hu et al., 2018). Here, we investigate the nocifensive response to SNI in both male and female mice using mechanical and thermal measures. Interestingly, removal of TLR4 only on Nav1.8<sup>+</sup> nociceptors delay the onset of mechanical hypersensitivity but not cold allodynia in female mice. Additionally, re-expression of TLR4 on these same nociceptors confers a phenotype that recapitulates a wild type behavioral response to neuropathic injury only in females. Lastly, whole body knockouts of TLR4 in both sexes behave similarly, conferring necessity during the onset of neuropathic pain in both sexes. Together, these data indicate that neuronally-expressed TLR4 is both necessary and sufficient during the onset of neuropathic mechanical hypersensitivity. The involvement of TLR4 signaling in thermal hyperalgesia is unclear. TLR4 deficiency has been shown to reduce mechanical allodynia, but not

thermal hyperalgesia in a model of trigeminal neuropathic pain (Hu et al., 2018). Conversely, administration of a TLR4 antagonist, lipopolysaccharide (LPS)-RS, after chronic constriction injury (CCI) reduced both mechanical allodynia and thermal hyperalgesia (Jurga et al., 2016). We report no significant differences in cold allodynia, measured by behavioral response to acetone application, throughout the entirety of our behavioral experiments, independent of both sex and genotype. Interestingly, a recent study highlights how over 80% of cold-sensitive neurons in the DRG do not express Nav1.8 (Luiz et al., 2019). As we study the role of TLR4 in the Nav1.8 expressing neuronal population, it is a potential that co-expression between TLR4 and cold sensitive neurons (TRPM8) is not high enough to confer biological relevant behavioral changes in a murine model of neuropathic pain.

A major unanswered question from this work is how the spontaneous ectopic activity of Nav1.8<sup>+</sup> DRG neurons is affected by direct TLR4 activity following neuropathic injury. Our histological data provides some insights as to what molecular changes these neurons undergo soon after injury, however; changes in their excitability are unknown. Following SNI, there is a large increase in the spontaneous activity of DRG neurons in addition to afferent fibers in the injured sciatic nerve (Seltzer et al., 1990; Wall & Gutnick, 1974). As seen in our model and consistent with others, whole body knockouts of TLR4 exhibit attenuated pain responses following injury (Piao et al., 2018; Tanga et al., 2005). While we currently cannot pinpoint the effects of direct TLR4 activation on DRG neuron excitability, there is evidence in the brain where TLR4 activation leads to increased neuronal excitability in the dentate gyrus after injury (Li, Korgaonkar, et al., 2015). Although not directly translatable, this does provide compelling

evidence that TLR4 can modulate neuronal excitability. Therefore, understanding the role of TLR4 in regulating the spontaneous activity and subsequent excitability of DRG nociceptors will yield significant insights as to how the transient changes in behavior we see evolves into long-term nociceptor plasticity. This is a research endeavor we plan on pursuing as a follow-up to the present study.

In conclusion, we have identified a novel and sexually dimorphic mechanism of neuronal injury in a murine model of neuropathic pain. Female, but not male mice utilize endogenous TLR4 activation on their Nav1.8 expressing nociceptors to facilitate the onset of mechanical hypersensitivity following SNI. Additionally, TLR4 expression on Nav1.8 expressing nociceptors plays an important role in regulating neuronal localization of HMGB1 in female mice. Taken together, these data indicate a unique mechanism of neuronal injury and behavioral output following peripheral injury in female mice. This work is poised as an initial endeavor into the sexually dimorphic mechanisms that regulate pain plasticity.

## CHAPTER 6

### SUMMARY AND SIGNIFIGANCE

In the last few years there has been a significant push towards uncovering the mechanisms that facilitate sex differences in pain. With the increased focus on including biological sex as a variable in pre-clinical studies numerous studies have provided valuable insights as to how the cellular mechanisms between males and females differ. Microglia were initially ascribed as the primary mediator of sex-dependent differences in pain development (Sorge, 2011; Sorge, 2015). However, numerous studies that followed suite have provided robust evidence that the peripheral immune and nervous systems influence these nociceptive circuits in a sex-dependent manner more than we previously believed (Lopes, 2017; Peng, 2016; Szabo-Pardi et al., 2021; Woller et al., 2015; Woller et al., 2016; Yu, 2020; Zhang et al., 2016). Signals that arise from the DRG are modulated by a plethora of neuro and immunomodulatory molecules which rely on bidirectional communication between the nervous and immune systems. Inflammatory mediators such as CSF1, CCL2, HMGB1, IL-6, IL-1 $\beta$  and TNF $\alpha$  are all upregulated to varying degrees during CIPN, surgery-induced neuropathy and inflammation and modulate the nociceptive system in various sex- and cell-specific ways. Our lab and others have demonstrated that robust sex differences related to TLR4 signaling exist in both central and peripheral systems which are responsible for mediating chronic pain development (Agalave et al., 2021; Agalave, 2020; Huck et al., 2021; Sorge, 2011; Szabo-Pardi et al., 2021; Woller et al., 2016).

Literature over the last few decades as shown a significant correlation between expression, upregulation, and modulation of HMGB1 and various forms of chronic pain (Lotze & Tracey,

2005; O'Connor et al., 2003; Park et al., 2004; Yamasoba et al., 2016). We, and others, believe that endogenous danger signals such as HMGB1 have a prominent sex- and cell-specific role in mediating the development of neuropathic pain (Agalave et al., 2014; Agalave, 2020; Rudjito, 2020; Szabo-Pardi et al., 2021). The data presented throughout this dissertation suggests that the inflammatory signaling pathways differ between sexes where TLR4 activation on male peripheral macrophages mediates inflammation and neuropathic pain development, whereas direct activation of TLR4 on female nociceptors is responsible for these effects. This work serves as a foundation in the Burton Lab for future research aimed at dissecting sex- and cell-specific mechanisms of chronic pain development and subsequent therapeutic targets.

## **BIOGRAPHICAL SKETCH**

Thomas is currently enrolled in the PhD program at The University of Texas at Dallas and is pursuing a career as a technical applications scientist in the industrial sector. His meticulous attention to detail and desire to discover optimal and efficient solutions for not only research endeavors, but also scientific protocols, has prepared him to improve the research community by providing support and guidance as he takes a step away from the bench. His desire to study neuroimmunology stems from an early exposure to pre-clinical research during his time spent working in Drs. Theodore Price and Gregory Dussor's Pain Neurobiology Research Group. As an undergraduate researcher, he worked closely with graduate and post-doc mentors on NIH funded research projects modulating the activity of cellular metabolism and determining its efficacy in treating both acute and chronic pain. The opportunity to work closely with well renowned investigators in the field as an undergraduate researcher helped him develop a strong foundation of not only technical skills, but also life skills necessary to pursue a successful career in science, as well as the knowledge to provide meaningful contributions to the field along the way. To that end, the positive experiences he encountered during his undergraduate education inspired him to pursue a doctoral degree in neuroscience under the tutelage of Dr. Michael Burton, whose primary research interests included the intersection of both the nervous system and immune system, with a focus on the interconnected dynamics of neuroimmune signaling in mediating chronic pain. His diverse background and experiences allowed Thomas to pursue both of his passions, neuroscience and immunology, to their fullest potential.

Over the past 5 years as a graduate student, Thomas has worked on numerous projects tailored towards understanding how cell-specific mechanisms during the development of chronic pain are

sexually dimorphic by nature. Until a recent NIH mandate, pre-clinical pain research had been conducted in almost exclusively male subjects, creating an immense void in knowledge considering the mechanistic differences in cellular machinery between males and females. Under the shadow of the current opioid crisis, the lack in efficacy of non-opioid based pain therapeutics in the clinic leaves many questions unanswered. Thomas' research sought to provide a better understanding of the inherent mechanistic differences between sexes that mediate chronic pain development. This dissertation has provided robust preclinical evidence that suggests there are numerous sex differences in the cellular response during chronic pain development. Specifically, a dichotomy exists between sexes in their neuronal and immune-mediated response to tissue injury and inflammation. His experiences thus far have exposed him to the highest caliber of neuroscience research and have provided the necessary skillset to pursue a professional career in science.

## CURRICULUM VITAE

**Thomas Alexander Szabo-Pardi**  
**Behavioral and Brain Sciences**  
**The University of Texas at Dallas**  
**800 W Campbell Road, Richardson, TX 75080**

### **Chronology of Education:**

- 2017-2022      Doctor of Philosophy  
The University of Texas at Dallas  
Mentor: Michael D. Burton, Ph.D.  
Field of Study: Neuroscience
- 2017-present      Master of Science  
The University of Texas at Dallas  
Mentor: Michael D. Burton, Ph.D.  
Field of Study: Neuroscience
- 2013-2017      Bachelor of Science  
The University of Texas at Dallas  
Mentor: Theodore J. Price, Ph.D.  
Field of Study: Neuroscience

### **Chronology of Employment**

- 2020-2022      Graduate Teaching Assistant  
The University of Texas at Dallas  
Department of Behavioral and Brain Sciences
- 2019-2020      Graduate Research Assistant  
The University of Texas at Dallas  
Mentor: Michael D. Burton, Ph.D.  
Field of Study: Neuroscience
- 2017-2019      Graduate Teaching Assistant  
The University of Texas at Dallas  
Department of Behavioral and Brain Sciences
- 2016-2017      Research Intern  
The University of Texas at Dallas  
Mentors: Theodore J. Price & Gregory O. Dussor  
Field of Study: Neuroscience
- 2014-2016      Volunteer Undergraduate Researcher

The University of Texas at Dallas  
Mentors: Theodore J. Price & Gregory O. Dussor  
Field of Study: Neuroscience

### **Academic and Professional Honors**

2020 Santrock Conference Travel Award  
2019 Brain and Behavioral Sciences Ph.D. Travel Award  
2017 PVST Brain and Behavioral Sciences Scholarship

### **Grant Applications**

2021 F31 Ruth L. Kirschstein National Research Service Award (NRSA)  
predoctoral fellowship (not funded)  
2020 F31 Ruth L. Kirschstein National Research Service Award (NRSA)  
predoctoral fellowship (not funded)

### **Professional Collaborations**

2021-2022 Abbott Laboratories

### **Professional Societies**

2018-present International Association for the Study of Pain  
2017-present American Pain Society  
2016-present Society for Neuroscience

### **Publications**
