PROBING DYNAMIC CELLULAR PROPERTIES USING GENOME EDITING AND
SYSTEMS BIOLOGY

by

CHANCE MICHAEL NOWAK, BS, MS

DISSERTATION

Presented to the Faculty of
The University of Texas at Dallas
in Partial Fulfillment
of the Requirements
for the Degree of

DOCTOR OF PHILOSOPHY IN
MOLECULAR AND CELL BIOLOGY

THE UNIVERSITY OF TEXAS AT DALLAS

December 2021

ACKNOWLEDGMENTS

I would first like to thank my parents, Tim and Teri, for their continued love, support, and encouragement. I am grateful for the opportunities you have granted me to pursue my doctoral degree. It has been a long road, and you were there every step of the way to push me when it was most crucial. I would also like to thank my fiancée, Apoorva, for her support, love, and affection, especially in the most trying times throughout this journey. Your persistent encouragement has been a cornerstone to my perseverance, and I could not be more grateful. I would like to thank my supervisor, Leo. You have afforded me opportunities that would otherwise have been unattainable, and you have instilled in me an appreciation for utilizing engineering practices for addressing biological problems. Thank you for the privilege of working in your lab, and for allowing me to work with so many outstanding scientists. I would like to thank my lab members for their support and collaborations throughout my doctoral degree, especially Yi who has helped guide me through my experiments to make me a better scientist. Lastly, I would like to thank my dear friends Jude, Eric, John Henry, Luke, Michael, and Taek. I could not have done this without your friendship, which has been invaluable.

PROBING DYNAMIC CELLULAR PROPERTIES USING GENOME EDITING AND
SYSTEMS BIOLOGY

Chance Michael Nowak, PhD
The University of Texas at Dallas, 2021

Supervising Professor: Leonidas Bleris

Genome editing has revolutionized not only the future of biological research, but also holds the promise of being a powerful therapeutic for genetic diseases. When considering the multitude of genetic regulations that contribute to various biological processes and their individual contributions that permit diseased cellular states, especially in instances where more than a single genetic aberration is attributed to the diseased phenotype, it is crucial to consider the interconnectivities of gene regulators and their individual contributions to cell health. Biological network maps that reveal the relation of gene products to one another can provide insight into the biological properties they govern. A biological network map consists of nodes (gene products) connected by edges that are dictated by the nature of the interaction between the two nodes. Nodal ablation (i.e., knocking out a gene to render it non-functional) has been crucial in understanding diseased states. However, this type of mutational analysis essentially disregards the impact that individual edges have on the network as a whole. The goal of my dissertation work was to utilize the genome editing tool Cas9 to disrupt the p53-miR-34a network in an edge-specific manner in order to demonstrate not only the complexity of these networks, but to also

underscore the importance that individual edges have on the tumor suppressor phenotype. To this end, I, along with a team of researchers, developed a genetic screen using Cas9-bearing lentiviral vectors to disrupt 93 miR-34a binding sites within the 3' untranslated region (UTR) of 71 genes impactful to cell survival under apoptotic conditions. I quantified the degree of apoptosis in two colorectal cancer cell lines that differ in functional p53 status, and that each harbored miR-34a binding site mutations within the pro-survival gene Bcl-2 3'UTR, demonstrating the importance of the miR-34a-Bcl-2 edge on apoptotic progression. Concurrently, I investigated the phenomenon of cell cycle desynchronization by tracking the DNA distribution of a population of cells starting from a synchronized state until asynchrony with flow cytometry analysis. In doing so, I utilized statistical tools to quantify the degree of desynchronization that does not rely on individual cell cycle phase labeling. Additionally, with the help of my peers, tested and validated a mathematical model that recapitulates experimental observations. I explored the sensitivity of the model to changes in its parameters to reveal that cell cycle variability within the population is a main contributor to cell cycle desynchronization. Furthermore, I tested this model prediction by treating cells with lipopolysaccharide to enhance cellular noise, resulting in a greater variability of cell cycle duration, which was also shown to increase the rate of cell cycle desynchronization. Taken together, my research provides insight into the importance individual edges have to biological networks and their resulting phenotypes, as well as the underlying sources of cell population heterogeneity and its contribution to cell cycle variability.

LIST OF ABBREVIATIONS

ASF	auto-similarity function
BrdU	bromodeoxyuridine
Cas	CRISPR associated protein
CDF	cumulative distribution function
CDK	cyclin dependent kinases
CPM	counts per million
CRISPR	Clustered Regularly Interspaced Short Palindromic Repeats
crRNA	CRISPR RNA
EIV	error-in-variables
GC	growth control
HR	homologous recombination
lncRNA	long non-coding RNA
LPS	lipopolysaccharide
miRNA	microRNA
MOI	multiplicity of infection
mRNA	messenger RNA
NGS	next generation sequencing
NHEJ	non-homologous end-joining
NUC	nuclease lobe
ORF	open reading frame
PAM	protospacer adjacent motif
PCR	polymerase chain reaction
PI	PAM-interacting domain
PI	propidium iodide
PS	phosphatidylserine
qRT-PCR	quantitative reverse transcription PCR
REC	recognition lobe
RISC	RNA induced silencing complex
RNAP	RNA polymerase
RNP	ribonucleoprotein
R-point	restriction point
sgRNA	single guide RNA
SpCas9	Streptococcus pyogenes Cas9
TP	transition probability
tracrRNA	transactivating CRISPR RNA
UTR	untranslated region

CHAPTER 1

INTRODUCTION

1.1 Author contributions

Chance M. Nowak prepared this chapter. A section of this chapter is reused from the original manuscript “Guide RNA engineering for versatile Cas9 functionality”. The open-access article distributed under the terms of the Creative Commons Attribution License allows the reuse of portions of the full article as a part of the author’s dissertation. Oxford University Press, *Nucleic Acids Research*, Volume 44, Issue 20, 16 November 2016, Pages 9555–9564, DOI: 10.1093/nar/gkw908

1.2 Biological networks: nodes vs edges

The complex, overlapping macromolecular interactions, whether it be physical or biochemical, dictate all aspects of biological processes and can be depicted as an interaction network map. Biological network maps consist of nodes and edges, in which nodes are the gene product and their functional relation to other nodes is described by the nature of the edge (**Figure 1.1a**). Networks can depict multiple cellular processes from protein-protein, protein-DNA, RNA-RNA, or amalgamation of all the aforementioned interactions. The interconnectivity of nodes via edges can reveal molecular interactions that govern specific molecular processes that manifest as observable phenotypes. Highly connected nodes (a node with many edges) are generally referred

to as hubs and are typically genes or gene products that are essential to a particular biological process.

Mutations that completely inactivate a gene or render the gene product nonfunctional can be viewed as a nodal ablation, and loss of highly connected hubs can reveal the biological processes the given node governs. Analogously, the classic mutational analysis approach typically seeks to inactivate genes, which has been pivotal in elucidating the biological function of genes, particularly in instances of monogenic diseases in which the functional loss of a given gene removes all of the interconnected edges and the network essentially collapses and the loss of the biological process is detected as a clear observable phenotype (**Figure 1.1b**). However, this type of network analysis does not capture the full range of potential biological malignancies. Indeed, there are multiple instances in which edge perturbations can “rewire” biological networks resulting in phenotypic changes (Sahni et al. 2013).

For example, genetic mutations that exhibit gain-of-function traits are essentially gene products that have gained new edges distinct from the their unperturbed interactome counterpart (**Figure 1.1c**). The tumor suppressor transcription factor p53 can mutate such that it in contrast to its usual transcriptional activation of genes involved in DNA damage response, cell cycle arrest, and programmed cell death (apoptosis) can, through altered binding specificity, upregulate pro-survival and proliferation-enhancing gene products that significantly alter the canonical p53 interactome (C. Zhang et al. 2020). Missense mutations within the DNA-binding domain of p53 can lead to alternative binding that results in upregulation of cell cycle progression genes in

response to DNA damage (Di Agostino et al. 2006), thus propagating mutations that can lead to genomic instability.

Similarly, edges can be lost through missense mutations that have significant impact on disease phenotypes (Zhong et al. 2009) (**Figure 1.1d**). For example, a missense mutation in the p53-inhibitor, Mdm2, can result in the inability to bind to ribosomal proteins associated with ribosomal stress, which ordinarily would lead to p53 activation (Macias et al. 2010).

Interestingly, Mdm2 can still regulate p53, under DNA damaging conditions for instance, but loses the ability to regulate it under ribosomal stress in particular. This results in a failure of p53 to become active under ribosomal stress, leading to sustained c-myc (proto-oncogene)-mediated upregulation of proteins involved in ribosome biogenesis contributing to tumorigenesis (Macias et al. 2010). It is therefore pivotal to not just understand the interconnectivity of nodes, but to consider the nature of the “edgetic” interactions in order to build complete mechanistic details that govern specific biological processes, especially those integral to diseased states (Zhong et al. 2009).

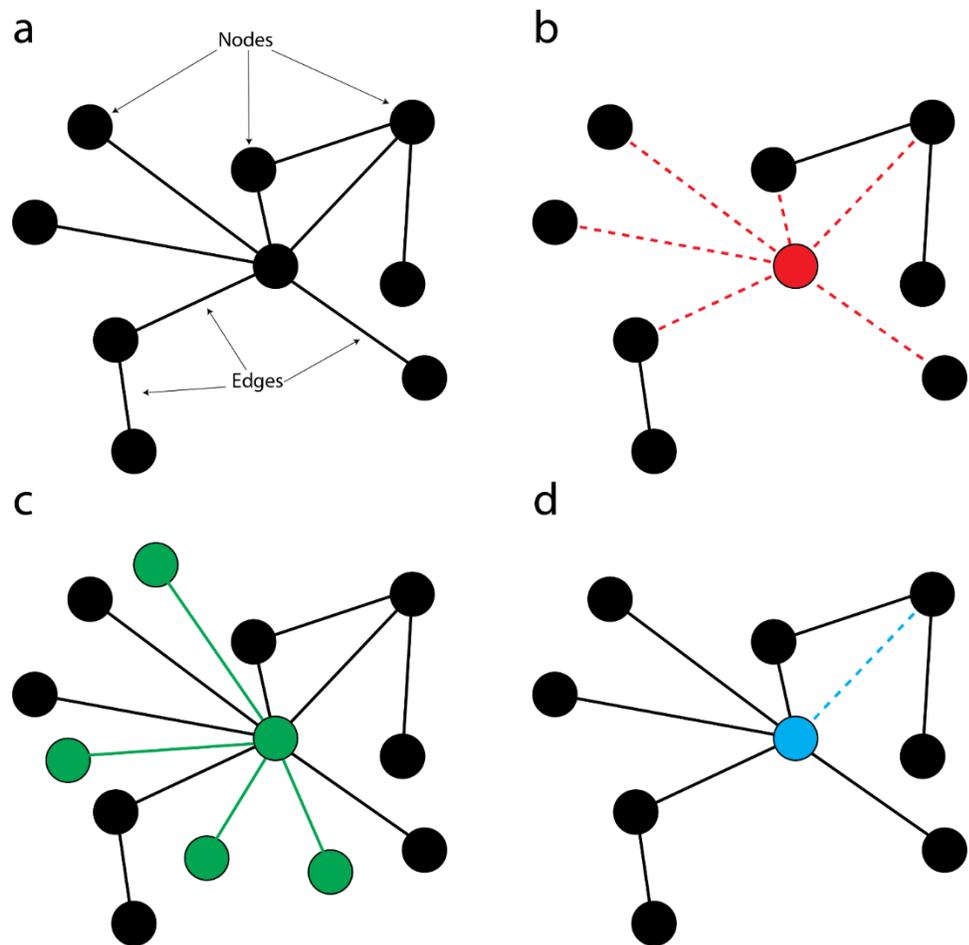

Figure 1.1: Biological network map demonstrating node- and edge-specific mutations. a) intact wildtype network consisting of nodes (i.e., gene and gene products) and edges (i.e., regulatory interaction) with a central hub (highly connected node) that functional regulates multiple nodes. b) mutation of hub that renders the gene completely nonfunctional removes all edge interactions, collapsing the entire network. c) mutation of hub that results in gaining new edges (e.g., mutated transcription factor that binds alternative DNA sequences, resulting in transactivation of new genes. d) mutation of hub that results in loss of edge (e.g., mutated sensory response protein, resulting in compromised network regulation)

Perturbing networks by augmenting edgetic interactions holds great promise for understanding the properties of the network as a whole. When considering mutational perturbations for edge function and relation, it is crucial to preserve the overall function of the nodes connected to the given edge. Gene structures contain regions that are not involved in the protein functions itself,

but do contain regulatory motifs that are directly responsible for the degree of expression, particularly in instances of responding to environmental cues. Thus, there is a unique opportunity to investigate these regulatory interactions without compromising protein function, while understanding what conditions are edges crucial to cell state and environmental responses. An attractive network for edge investigations would be a network that contains hubs with high connectivity that respond to changes in cellular state in highly phenotypic manner. One such network paradigm are microRNA networks, as not only can some miRNA networks be highly connected (hundreds of interactions) but can respond to cellular states. In the next section, a prominent miRNA network will be discussed with the emphasis on the method of regulation miRNAs confer as well as the states under which they are induced (e.g., cellular stress) with robust phenotypic reactions.

1.3 p53 and miR-34a

microRNAs (miRNAs) are a class of small non-coding RNAs ~22 nucleotides (nt) in length that post-transcriptionally regulate gene expression through translational repression. miRNAs must go through extensive processing before becoming functionally mature and are processed in a step-wise and compartmentalized fashion with biogenesis beginning in the nucleus as long hairpin structures that are extensively processed (trimmed to shorter hairpin structures) before being exported to the cytoplasm for further processing in and trimming and strand separation (removing the hairpin structure) (Bohnsack, Czaplinski, and Gorlich 2004). Ultimately, the miRNA is trimmed down to a mature 22 nt double-stranded RNA in the cytoplasm, which then associates with a member of the Argonaute protein family, namely Ago1-4 with Ago2 being

functionally distinct by its endonuclease activity (Höck and Meister 2008; Ruda et al. 2014). Of the two strands, one acts as a guide strand and the other a passenger strand, with the latter being degraded while the guide strand tightly associates to the Ago protein to form the RNA induced silencing complex (RISC) (Marzi et al. 2016). The guide strand dictates which mRNA substrates the RISC binds, and is largely dependent on partial complementary base pairing with a small ~7 nt “seed” sequence typically found in the mRNA’s 3’ untranslated region (UTR) (Brennecke et al. 2005), although non-canonical (i.e. seed-independent) binding interactions have been shown to occur (Seok et al. 2016; Clark et al. 2015). In canonical mRNA-RISC interactions, this seed region has been shown to be a crucial determinant of which mRNAs to target, and such a relatively small determinant enables some miRNAs to have a multitude of targets, with some miRNAs predicted to have hundreds (Lim et al. 2005; David P Bartel 2009).

Some miRNAs are basally expressed in the cells to constrictively curb gene expression of some gene products. Other miRNAs are highly inducible depending on the cellular state. For example, DNA damage can result in the acquisition of multiple mutations, and while there are sophisticated DNA repair pathways to ameliorate this cellular stress, under extreme conditions, however, the cell may not be able to repair the damage abruptly, thus necessitating a halt on cell cycle progression, or in some cases the damage may be so severe that the cell self-destructs in order to prevent the propagation of these mutations to daughter cells. One highly connected node that serves as a hub for this response process is the p53 protein that actively upregulates the transcription of miRNAs to downregulate a host of genes.

p53 is a transcription factor that is crucial in maintaining genome integrity, and has earned the title as guardian of the genome (Lane 1992). In response to cellular stress such as DNA damage, p53 activation induces cell cycle arrest allowing the cell to repair the damage before any mutations can be propagated; if the damage is beyond repair, p53 will initiate programmed cell death (apoptosis) to prevent the propagation of a compromised genome. These anti-proliferative functions of p53 are well documented (Muller and Vousden 2013; Biegging, Mello, and Attardi 2014), and accordingly, most human cancers have been found to acquire a mutated or dysfunctional p53 (Hainaut and Hollstein 1999). Furthermore, the importance of p53 in tumor suppression is underscored by the activation of target genes that suppress cell proliferation and promote apoptosis. p53 can exert cell cycle arrest by transactivating the expression of potent cyclin-dependent kinases (CDKs) inhibitors such as p21, p27, and p16 (Polager and Ginsberg 2009; G. He et al. 2005) that regulate of the transition of G₁ to S phase. Not only can p53 regulate cell fate by transactivating inhibitors of key cell cycle regulatory proteins, but also can transactivate the expression of miRNAs that directly repress genes involved in cell cycle progression, proliferation, and pro-survival, such as miRNA-34a.

RISC-mediated silencing has been implicated in most, if not all, cellular processes from mammalian development to disease (Kloosterman and Plasterk 2006). In relation to disease, specifically cancer, some miRNAs can be classified as oncogenic or anti-oncogenic (B. Zhang et al. 2007). One prominent miRNA that exhibits tumor suppressive functions is miR-34a (Rokavec et al. 2014; Bader 2012; Hermeking 2010). miR-34a expression is strongly associated with cell cycle arrest and apoptosis. A subset of miRNA-34a targets are those involved in the cell cycle

progression at the G₁-S phase transition, of which include proto-oncogenes such as c-myc (Christoffersen et al. 2010; Sotillo et al. 2011; Yamamura et al. 2012), CDK4 (Hargraves, He, and Firestone 2016; Tianyou Wang 2014; Guo et al. 2015) and CDK6 (Navarro et al. 2009; Yunqing Li et al. 2009; Sun et al. 2008), and cyclins E2 (Lin He et al. 2007; Sun et al. 2008) and D1 (Sun et al. 2008; Hermeking 2010). Unsurprisingly, miR-34a-mediated regulation of the G₁/S phase transition can be induced by the tumor suppressor protein p53, due to the presence of the p53 response element located near the miR-34a transcriptional start site (Chang et al. 2007; Concepcion et al. 2012). miR-34a is also involved in repressing the expression of proliferation promoting genes such as SIRT1 (Yamakuchi, Ferlito, and Lowenstein 2008), which can inactivate the p53 protein via deacetylation, and pro-survival genes such as BCL-2 (Lin et al. 2014), which inhibit proteins that initiate apoptosis. Interestingly, while miR-34a is transactivated by p53 resulting in repression of cell cycle regulators of the G₁/S transition in a redundant fashion to p53 upregulation of CDK inhibitors, miR-34a can also exhibit antiproliferative functions independent of p53 functional status (i.e., wildtype p53).

Importantly, given the prevalence of p53 inactivation as well as gain of function mutations in multiple cancer types it is worth considering modes of treatment that allow p53-independent functional interactions as potential therapeutics. While miR-34a is highly connected to p53 activity, it is worth noting that there are reported incidents of miR-34a tumor suppressor activity independent of p53 status, that is miR-34a has shown to be activated without functional p53 status (Zhao et al. 2013; Christoffersen et al. 2010; Tazawa et al. 2007).

Thus, the p53-miR-34a network seems to be an ideal candidate for edgetic interventions given its robust phenotypes, namely cell cycle arrest as well as promoting cell death, as well as its response to cellular states, such as cell stress, and lastly the highly interconnected edges that make up this network. The question then becomes, how can we perturb these regulatory interactions in a precise manner? One such manner is genomic intervention via genome editing such as the programmable nuclease Cas9 to independently and systematically remove these edges in a way that does not compromise the function of the individual nodes that describe these relations. Interestingly, however, while the tumor suppressor p53 is constitutively expressed, the protein is rapidly degraded due to the p53 inhibitor E3 ubiquitin ligase Mdm2 (Kubbutat, Jones, and Vousden 1997; Haupt et al. 1997), and despite studies that have demonstrated post-transcriptional regulation motifs within the p53 3'UTR via reporter assays (Haronikova et al. 2019), genomic deletion of the endogenous p53 3'UTR was shown to have no impact on p53 translation under normal conditions or following DNA damage (Mitschka and Mayr 2021). Thus, highlighting the importance of genomic perturbations in native gene contexts for elucidating the impact of regulatory elements over synthetic gene reporter constructs (such as luciferase or fluorescent proteins). In **Chapter 2**, genomic editing of edge-specific interactions within the p53-miR34a are explored further.

1.4 SpCas9 as genome editing tool

1.4.1 SpCas9 endogenous system

The Clustered Regularly Interspaced Short Palindromic Repeats (CRISPR) system allows a single guide RNA (sgRNA) to direct a protein with combined helicase and nuclease activity to the DNA. *Streptococcus pyogenes* Cas9 (SpCas9), a CRISPR-associated protein, has revolutionized our ability to probe and edit the human genome in vitro and in vivo. CRISPR loci are present in prokaryotes, including both bacteria and archaea (Horvath and Barrangou 2010; Garneau et al. 2010), and are primarily characterized by direct repeat sequences interspaced by similarly sized variable sequences (Sorek, Kunin, and Hugenholtz 2008; Brouns et al. 2008; Barrangou et al. 2007; Jansen et al. 2002). Early investigations into the nature of the repeat and variable sequences revealed that CRISPR and the CRISPR-associated proteins (Cas) work in tandem to recognize and cleave invading foreign DNA (Barrangou et al. 2007; Lander 2016; Brouns et al. 2008; Jansen et al. 2002; Sorek, Kunin, and Hugenholtz 2008; Deveau et al. 2008; Garneau et al. 2010; Horvath and Barrangou 2010). The characterization of CRISPR-Cas as a type of prokaryotic immune system laid the groundwork for what has now become a powerful tool for various applications well outside the original biological context (Mali et al. 2013b; Le Cong et al. 2013; Niu et al. 2014; Hai et al. 2014; Richard Moore et al. 2015; Yi Li et al. 2016; Hilton et al. 2015; Jinek et al. 2013).

In prokaryotes, the CRISPR-Cas system functions as a microbial analog to the acquired (adaptive) immune system present in higher organisms (Barrangou et al. 2007; Bolotin et al. 2005; Makarova et al. 2006). The variable sequences of the CRISPR array, known as spacers, are

relics of previous infectious events whereby fragments of invading DNA, or protospacers, have been captured and integrated into the host genome at the CRISPR locus to serve as an immunological memory (Deveau et al. 2008). Once a new protospacer has been integrated into the CRISPR array, the entire array can be transcribed into pre-crRNA and processed into mature crRNA.

The processing of pre-crRNA into mature crRNA is distinct in type II CRISPR systems in that it relies on the presence of trans-activating crRNAs (tracrRNAs) that hybridize with the pre-crRNA through complementary base pairing to the repeat regions (Deltcheva et al. 2011; Gasiunas et al. 2012; Jinek et al. 2012). RNase III, a dimeric endoribonuclease that cleaves double-stranded RNA, then recognizes the pre-crRNA:tracrRNA hybrid and cleaves individual crRNA:tracrRNA hybrids from the primary CRISPR array transcript (Deltcheva et al. 2011). Ultimately the crRNA-tracrRNA hybrid spacer sequence (**Figure 1a**) is trimmed down to 20 nucleotides (Deltcheva et al. 2011) before tightly associating with the SpCas9 nuclease and forming the catalytically active ribonucleoprotein (RNP) complex used for targeted DNA cleavage (Bolotin et al. 2005; Makarova et al. 2006).

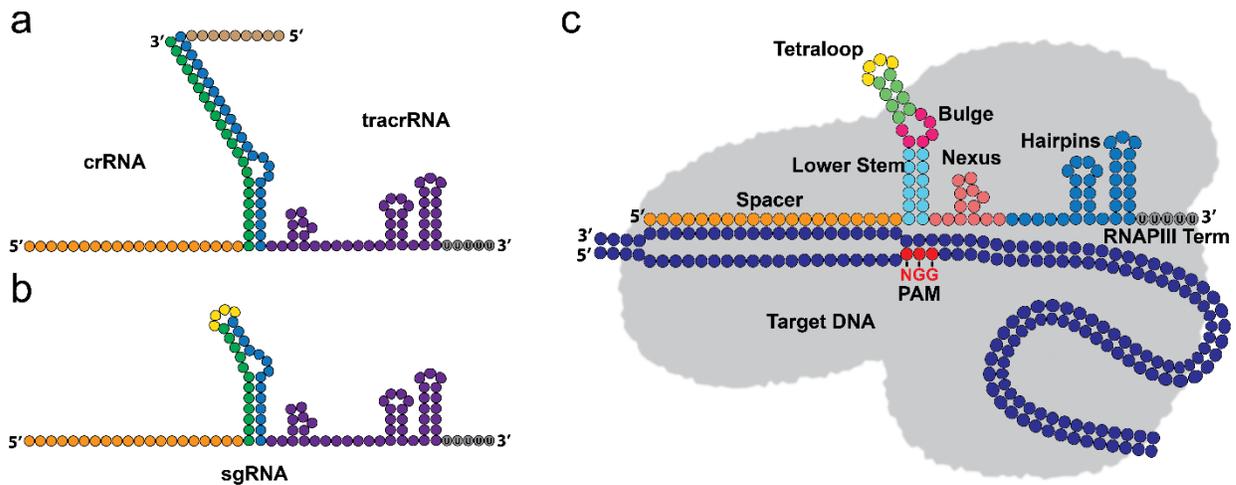

Figure 1.2: *S. pyogenes* CRISPR-SpCas9 guide RNA anatomy. (a) Endogenous CRISPR RNA (crRNA) and transacting crRNA (tracrRNA). The spacer sequence (orange) is 20 nucleotides in length and the repeat sequence (green) is 22 nucleotides that basepairs with tracrRNA complementary region (blue). The 3' handle region (purple) has functional significance for structure-dependent recognition by SpCas9. (b) The synthetic sgRNA retains dual-tracrRNA:crRNA secondary structure via a fusion of the 3' end of the crRNA to the 5' end of the tracrRNA with an engineered tetraloop. (c) Individual functional modules of the sgRNA (sgRNA structure adopted from Briner et al., 2014). The 5' spacer sequence dictates SpCas9 localization within the genome. The lower stem is formed by the duplex between the CRISPR repeat sequence from the crRNA and the region of complementarity in the tracrRNA. SpCas9 interacts with the upper and lower stems in a sequence-independent manner, whereas the bulge interactions with SpCas9 appear to be sequence-dependent. The nexus contains both sequence and structural features necessary for DNA cleavage and lies at the center of the sgRNA:SpCas9 interactions. The nexus also forms a junction between the sgRNA and both SpCas9 and the target DNA. The terminal hairpins assist in stabilizing the sgRNA and supports stable complex formation with SpCas9.

An indispensable aspect of any immune system is the ability to distinguish self from non-self; in other words, the components of the immune system must be able to recognize molecules that do not originate from the host. The SpCas9 CRISPR system achieves this distinction through the recognition of a protospacer adjacent motif (PAM), which is a short G-rich oligonucleotide sequence downstream of the target DNA (Deveau et al. 2008; Marraffini and Sontheimer 2010). This feature is crucial for targeted DNA cleavage, as the corresponding spacer in the CRISPR

array is identical to the target DNA, and would otherwise be cleaved. It is not until after SpCas9 scans invading foreign DNA for the PAM sequence 5'NGG that complementary base pairing between the target DNA and crRNA can occur and trigger targeted DNA cleavage (Mojica et al. 2009; Sternberg et al. 2014).

The high-resolution crystal structure of SpCas9 in complex with a sgRNA, and its cognate target DNA obtained by Nishimasu *et al.* identified key functional interactions that govern the molecular mechanism of SpCas9-mediated DNA cleavage. The crystal structure revealed that SpCas9 has a bilobed architecture composed of a Recognition lobe (REC) and a Nuclease lobe (NUC), and the site of heteroduplex formation between the sgRNA and its cognate target DNA is a positively charged cleft at the interface between the two lobes (Nishimasu et al. 2014; Jinek et al. 2014). The REC lobe is comprised of an α -helical region termed the bridge helix domain that recognizes the “seed” region (the 10-12 PAM-proximal nucleotides of the guide region) of the sgRNA through salt bridges with sgRNA backbone, a REC1 domain that recognizes repeat:anti-repeat duplex of the sgRNA, and the REC2 domain that does not interact with the guide:target heteroduplex. The NUC lobe is comprised of a RuvC catalytic nuclease domain that cleaves the non-complementary strand of the target DNA, a HNH catalytic nuclease domain that cleaves the complementary strand of the target DNA, and a PAM-interacting (PI) domain that recognizes the 5'NGG PAM on the non-complementary strand (Jinek et al. 2012; Nishimasu et al. 2014; Jinek et al. 2014; Gasiunas et al. 2012).

SpCas9 interacts with the sgRNA in both sequence-dependent and independent manners—the guide region is recognized in a sequence-independent mechanism, whereas SpCas9 recognition of the sgRNA repeat:anti-repeat duplex involves sequence-dependent interactions (Nishimasu et al. 2014). Additional information on the base pair interactions and details regarding conformational changes due to sgRNA and target DNA/PAM recognition can be found in recent literature (Nishimasu et al. 2014; Jinek et al. 2014; Sternberg et al. 2015; Anders et al. 2014).

1.4.2 SpCas9 genome editing in mammalian cells

Endogenous Type II CRISPR RNA components require extensive processing before becoming functional (Jinek et al. 2012; Gasiunas et al. 2012). The first effort to recapitulate the bacterial CRISPR system in mammalian cells involved the delivery of SpCas9, SpRNase III, the tracrRNA, and the pre-crRNA array, which contained the spacer sequence flanked by direct repeats (Le Cong et al. 2013). Interestingly, the inclusion of SpRNase III was found to be unnecessary for cleavage of the target DNA sequence in mammalian cells (Le Cong et al. 2013).

A key advance in CRISPR programmability came with the engineering of the chimeric single guide RNA (sgRNA) (Jinek et al. 2012). The chimeric sgRNA (**Figure 1b**) is a single transcript that retains the dual-tracrRNA:crRNA secondary structure via a fusion of the 3' end of the crRNA to the 5' end of the tracrRNA with an engineered tetraloop (Jinek et al. 2012). The most common approach to produce sgRNAs in human cells is using the human U6 RNA polymerase III (RNAP III) promoter (Mali et al. 2013b; Le Cong et al. 2013; Jinek et al. 2013). This constitutive RNAP III promoter allows the sgRNA transcript to escape post-transcriptional

modifications that are coupled to RNAP II transcription (such as 5' methyl capping and polyadenylation), which would otherwise result in its export out of the nucleus (Hamm and Mattaj 1990; McCracken et al. 1997).

The use of Cas9 and engineered sgRNA has served as a molecular toolkit that provided a foundation from which an innumerable number of applications have spurred. Applications using the wildtype SpCas9 include: gene knockout via targeting genes in their open reading frame (ORF) and subsequent error-prone DNA repair via the non-homologous end-joining (NHEJ) (L Cong et al. 2013; Mali et al. 2013a), regulatory motif ablation through NHEJ by targeting noncoding genetic regions (Yi Li et al. 2018; Hsieh et al. 2019), and gene knock-in with DNA fragments that contain regions of homology for targeted genomic integration via homologous recombination (HR) DNA repair (L Cong et al. 2013; Mali et al. 2013a). Additionally, Cas9 can be mutated to have nickase activity at the RuvC domain (D10A) or the HNH domain (H840A) resulting in single strand cleavage of the target strand or non-target stand, respectively (Jinek et al. 2012). Single strand nicking has recently been used in conjunction with deaminase fusions for single nucleotide base editing (Komor et al. 2016; Gaudelli et al. 2017) as well as fused to reverse transcription and elongated 3' gRNA for templated DNA repair (i.e., prime editing) (Anzalone et al. 2019). If both mutations are installed, Cas9 becomes nuclease deficient (dCas9) (Qi et al. 2013) and can be used as programmable DNA binding domain in which various functional proteins (or protein domains) can be fused to dCas9 for localized functional activity including: transcriptional activation (L. A. A. Gilbert et al. 2013), transcriptional repression (L.

A. A. Gilbert et al. 2013), epigenetic alterations (Hilton et al. 2015), fluorescent imaging of DNA (B. Chen et al. 2013).

While Cas9 has shown to be an indispensable tool for biological research into the function of genes, one promise intrinsic to the ability to alter genetic sequences with such precision is the use of genome editing intervention is use as a therapeutic to change genetic abnormalities. However, genetic alterations with genome editing tools ought to be used with consideration to p53 status (Haapaniemi et al. 2018). For example, one approach to utilizing genome editing tools such as Cas9 is to integrate Cas9 expressing constructs into the genome, which often harbor genetic antibiotic selection cassettes. Cells selected with the antibiotic in the presence of Cas9, which due to its nuclease activity, is considered cytotoxic, not only due to its on-target DNA cleavage, but additional off-targeted DNA cleavage can result in the inadvertent selection of nonfunctional p53 (Enache et al. 2020). As described previously, the p53 protein is a crucial regulator of DNA damage response, and can lead to cell cycle arrest in order to prevent the propagation of mutations from the subsequent daughter cells. Therefore, the artificial selection of the antibiotic resistance gene used to sustain Cas9 expression, which may persistently induce DNA damage, selects for p53 deficient cells, which may lead to further oncogenic activation (Conti and Di Micco 2018).

1.5 Cell cycle variability

While much attention has been focused on elucidating the cellular interactions that govern cell cycle regulation, one interesting phenomenon is the overall variability of cell cycle duration

within a population. Indeed, a great deal in effort has been investigating the source of heterogeneity within cellular populations to account for cell cycle variation (Robert F. Brooks 2021; D. A. Gilbert 1982; Perez-Carrasco, Beentjes, and Grima 2020; Alberghina, Mariani, and Martegani 1985; Koch 1980), and additionally, developing models that accurately describe cell population behavior, particularly the variability of the cell cycle. The cell cycle is a tightly regulated process that is mediated by multiple feedback networks (Pomerening, Kim, and Ferrell 2005; Gérard, Gonze, and Goldbeter 2012; Pomerening 2009; Ferrell and Jr. 2013) that enable oscillatory timing of events that result in the duplication of DNA and cellular division. Particular consideration has been focused on the genetic mechanisms regulating this process, especially the G_1/S transition, which is a critical point (termed the restriction point, or R-point) in the cell cycle in which the cell either commits to DNA synthesis, enters quiescence, or initiates apoptosis.

There are multiple factors that can contribute to the cellular fate of the cell, such as environmental cues, resource availability, and cell type. Interestingly, despite the highly regulated mechanisms that compute this decision, there exists noticeable variations in the timing of these events within a cellular population. Indeed, identical daughter cells that enter the cell cycle at the same time can have vastly different cell cycle durations. These overall variations in periodicity have been largely been attributed to the variable timing a given cell spends in the G_1 phase (especially in cell types that can exit G_1 and enter quiescence). Critically, cancer cells that have can highly dysregulated cell cycle regulatory mechanisms (Otto and Sicinski 2017; Leal-Esteban and Fajas 2020) can also demonstrate variability in the cell cycle duration. One realm of investigation to this phenomenon is to consider cellular noise in gene expression.

Gene expression noise can be divided into two sources: extrinsic and intrinsic. Extrinsic noise can arise from variations in cellular constituents such as transcriptional processivity or ribosome availability. Intrinsic noise arises from the inherent stochasticity of biomolecular interactions. Interestingly, multiple modes of thought have sought to provide an explanation for sources of cell cycle variability that also take into account cellular noise (Swain, Elowitz, and Siggia 2002; Zopf et al. 2013; Soltani et al. 2016; Gonze et al. 2018). Additionally, one of the crucial regulatory motifs of the G_1/S transition are bistable switches that are ultrasensitive to stochastic fluctuations (Yao et al. 2008b; T. J. Lee et al. 2010) that can commit a cell to engage in DNA synthesis. The variations in cell cycle periodicity are frequently analyzed through mathematical modeling, with an emphasis on incorporating sources of stochasticity to accurately capture cell cycle dynamics.

One of the earliest models proposed was the transition probability (TP) model (Smith and Martin 1973) used to describe entry into S phase from G_1 thus initiating DNA synthesis. This model postulates that the cell cycle is both probabilistic and deterministic. Specifically, the cell cycle was divided into an A state and a B phase. The B phase consisted of S, G_2 , and M which are deterministic in that once DNA synthesis starts in S phase it is committed to reaching G_2 (and ultimately mitosis if conditions are permissive). Thus, its duration is determinate. Whereas in the A-state, cells are not directed towards DNA synthesis and subsequent division, and as such can spend an indeterminate time within this state where the probability of leaving the A state at any time is constant. Therefore, the entry into S phase is dictated by a stochastic process, similar to the random radioactive decay of an atomic nucleus. However, this model had difficulties in

rectifying cells that enter quiescence (G_0) or from cells that are arrested at the R-point, and the model used a general strategy to describe these instances as just high or low probabilities of transition (Shields and Smith 1977). Later the model was updated to include an additional transition probability to account for quiescence cells, but is amenable to environmental factors such as serum deprivation and replenishment, which has shown to cause quiescent cells to reenter the cell cycle (R. F. Brooks, Bennett, and Smith 1980). Later, a second model was developed that posited that the duration of the entire cell cycle is largely dictated by the G_1 phase, and should be modeled separately from the rest of the cell cycle, i.e. the G_1 -rate model (Castor 1980) (later referred to as growth control model, GC). The model removes the unpredictable aspect of the transition model and instead attributes variability in S-phase reentry timing to differences in cell metabolism. The authors support this claim with the additional observation that the amount of RNA in a cell correlates with the rate of progression through initiation and completion of DNA synthesis, and the variability in G_1 arises from the capacity at which a cell can synthesize the proteins necessary for DNA replication. This thresholding description implicit in the GC model was later re-interpreted as an alternative description of the R-point (Cooper 2003). Interestingly, these two phenomenological models (TP and GC) largely escape the need for any mechanistic details, while still maintaining accurate descriptions of cell cycle control.

However, it was eventually shown that R-point is actually governed by bistable switch within the Rb-E2F pathway (Yao et al. 2008a), in which E2F (a master cell cycle transcription factor, and Rb its transcriptional repressor) is involved in two positive feedback motifs that put E2F in either

an ON or OFF state depending on nutritional availability (e.g. serum concentration). Later the activation of these ON or OFF states was shown to be stochastic, arising from intercell variability of gene expression such as intrinsic noise (e.g. stochastic nature of biochemical interactions within a cell) and extrinsic noise (e.g. heterogeneity in cellular components affected by environmental factors or cell age) (T. J. Lee et al. 2010; M. Elowitz et al. 2002). Importantly, the sensitivity to stochastic fluctuations could account for the inherent variability in cell cycle duration. This stochastic activation of the bistable switch controlling the R-point seems to reconcile differing aspects of the TP and GC models by extracting parameters from both models. Namely, the transition rate and time delay from the TP model, and mean growth rate and its variance from the GC model. Critically, simulated nodal perturbations of the Rb-E2F pathway led to changes in these parameters both predicted by their respective model.

These models have provided useful insight into the nature of cell population dynamics; moreover, the nature of the cell cycle heterogeneity gained further insight from the ability to synchronize cells to the same cell cycle phase and monitor cell cycle progression following synchronization. Indeed, investigations into cell cycle progression and regulation has often started with the need to synchronize all cells within a population to the same cell cycle phase. For example, the experiments in these early investigations described previously largely relied in serum deprivation for cell cycle synchronization. Another common approach to cell synchronization is the double thymidine block that interferes with nucleotide metabolism resulting in an inability of the cells to synthesize DNA causing a cell cycle arrest at the G₁/S boundary (Bjursell and Reichard 1973; G. Chen and Deng 2018).

One interesting observation discovered from observing the behavior of synchronized cell populations is that they desynchronize, and quickly reach a state of “asynchronicity,” whereby the individual cell cycle phases stabilize into fixed percentages. This phenomena has also been studied in cultured cells that were pulse labeled with bromodeoxyuridine (BrdU), thus creating a semi-synchronous cell population where only cells that are actively progressing through S-phase incorporate the thymidine analog BrdU into their genome, and thus can be tracked overtime by using a fluorescently conjugated BrdU antibody (Chiorino et al. 2001). These investigations hinted at the possibility of cell cycle variance (potentially manifesting from inherent cellular noise) as a contributor to desynchronization rates. Therefore, it is crucial to utilize mathematical models to capture cell cycle behavior at the population level to gain insight into the nature of cell cycle progression and regulation. In **Chapter 3**, the role of cell cycle variability with respect to the rate of cell cycle desynchronization is explored further.

1.6 Summary

Understanding the extent of cellular behavior in response to various conditions does not only lay the groundwork for understanding basic biological functions, but also provides insight in to how diseased cell states are acquired. Furthermore, the ability to describe these phenomena by representing biological pathways and processes via network analysis or mathematical modeling can lead to a greater appreciation of the highly organized and complex interactions and reactions that govern cell fate in a more holistic and approachable fashion. In this work, I present experimental results that support the contributions edges have to shaping overall networks through genome editing of miRNA target sites within the 3'UTR of genes involved in the p53-

miR-34a network. Additionally, I present experimental results coupled with in silico mathematical modeling to describe cell cycle desynchronization, and demonstrate that a main contributor of this process is cell cycle variability between cells, which may arise from stochastic sources of cellular noise.

CHAPTER 2

CRISPR-BASED EDITING REVEALS EDGE-SPECIFIC EFFECTS IN BIOLOGICAL NETWORKS

2.1 Author Contributions

The original manuscript was published along with Yi Li (YL), Daniel Withers (DW), Alexander Pertsemlidis (AP), and Leonidas Bleris (LB). YL and LB designed the experiments. YL, Chance Nowak (CN), and DW performed the experiments. YL, CN, AP, and LB analyzed the data. YL, CN, AP, and LB wrote the manuscript. LB supervised the project. Permission from YL was obtained for use of this manuscript in this dissertation in conjunction with © Mary Ann Liebert, Inc., *The CRISPR Journal*, Volume 1, Number 4, 4 November 2018, Pages 286-293, DOI: 10.1089/crispr.2018.0018.

2.2 Abstract

Unraveling the properties of biological networks is central to understanding both normal and disease cellular phenotypes. Networks consist of functional elements (nodes) that form a variety of diverse connections (edges) with each node being a hub for multiple edges. Herein, in contrast to node-centric network perturbation and analysis approaches, we present a high-throughput CRISPR-based methodology for delineating the role of network edges. Ablation of network edges using a library targeting 93 miRNA target sites in 71 genes reveals numerous edges that control, with variable importance, cellular growth and survival under stress. To compare the impact of removing nodes versus edges in a biological network, we dissect a specific p53-

microRNA pathway. We show that removal of the miR-34a target site from the anti-apoptotic gene BCL2 desensitizes the cell to ectopic delivery of miR-34a in a p53-dependent manner. In summary, we demonstrate that network edges are critical to the function and stability of biological networks. Our results introduce a novel genetic screening opportunity via edge ablation and highlight a new dimension in biological network analysis.

2.3 Introduction

We focus on the network formed by p53 and its upstream and downstream regulators, which is critical to cell health, yet incompletely understood. Since its discovery in 1979 (DeLeo et al. 1979), p53 has been shown to play a crucial role in maintaining genomic stability (Vousden and Prives 2009), with more than 50% of human cancers harboring mutant or deleted p53 (Levine 1997). Under normal conditions, the p53 protein exists in a latent form and at low concentration, but in response to various cellular stress signals such as DNA damage, hypoxia, and oncogene expression, post-translational modification of p53 results in its stabilization and accumulation (Batchelor, Loewer, and Lahav 2009). As most human malignancies shut down the p53 tumor-suppressing responses, p53 is one of the critical targets for drug interventions in cancer therapy (Parrales and Iwakuma 2015; Hong et al. 2014) .

A class of post-transcriptional regulators, called microRNAs (miRNAs), is directly associated with p53, either regulating the mRNA responsible for p53 production or being regulated by p53 and its partners (L He et al. 2007; Tarasov et al. 2007). miRNAs, in their mature forms, are small non-coding RNAs approximately 22 nucleotides in length that act as major regulators of gene

expression. Since miRNAs are involved in critical cellular and physiological processes such as growth, differentiation, apoptosis and metastasis, the gain or loss of critical miRNAs in a given cell type can have significant implications for cell fate (D P Bartel 2009; Filipowicz, Bhattacharyya, and Sonenberg 2008; Richard; Moore et al. 2015; J. Lee et al. 2014). Studies have revealed extensive crosstalk between the p53 network and miRNAs, but the specifics of how miRNAs participate in the regulation of p53 signaling and what they contribute to the role of p53 as a tumor suppressor remain largely elusive.

In miRNA-based networks, the edges are regulatory interactions between miRNAs and target mRNAs. These interactions are mediated by sequence complementarity and therefore are susceptible to genetic variation in either the miRNA or the target site – the seed sequence of the miRNA and the complementary region in the target site are considered the largest determinants of the interaction. Variation in miRNA binding sites has been associated with numerous diseases, including Tourette Syndrome (Abelson et al. 2005), rheumatoid arthritis (Chatzikyriakidou et al. 2010), lupus (Consiglio et al. 2011), psoriasis (Wu et al. 2011), Crohn’s disease (Brest et al. 2011; Kulkarni et al. 2013), Parkinson’s disease (G. Wang et al. 2008), hypertension (Sethupathy et al. 2007; Hanin et al. 2014), diabetes and obesity (Lv et al. 2008; Richardson et al. 2011), and multiple cancers (Ryan et al. 2015; Chin et al. 2008; Zu et al. 2013; Xiong et al. 2011; Pu et al. 2013). In the context of p53 signaling (Okada et al. 2014), miR-34a regulates HDM4, a strong repressor of p53, creating a positive feedback loop in which high levels of miR-34a de-repress p53, which in turn transcriptionally up-regulates the expression of miR-34a.

Network edges (e.g., miRNA-gene target interactions) are central to the function and stability of biological pathways. Today, we have the unprecedented opportunity to dissect individual cells and pathways with single-nucleotide specificity using genome editing. The most widely adopted editing methodology to date is the bacterial type II clustered regularly interspaced short palindromic repeats (CRISPR) system consisting of the CRISPR-associated protein Cas9 derived from *Streptococcus pyogenes* (SpCas9), a DNA endonuclease, and a guide RNA, which directs the binding of Cas9 to a DNA target upstream of a protospacer adjacent motif (PAM). The CRISPR technology has revolutionized our ability to probe and edit the human genome *in vitro* and *in vivo*, through targeted gene disruption, insertion, deletion, single-nucleotide mutation, and chromosomal rearrangement (Mali et al. 2013; Rong et al. 2014; J.-F. Li et al. 2013).

Furthermore, pooled sgRNA libraries can be used for versatile *in vitro* screening to investigate phenotypes of interest. Recent examples include screens identifying genes conferring drug resistance (Tim Wang et al. 2014), genes involved in metastasis (S. Chen et al. 2015), and long non-coding RNAs (lncRNAs) regulating human cancer cell growth (Zhu et al. 2016). Thus far, pooled sgRNA libraries have been applied to transcribed loci, which correspond to network *nodes*. Here, we selectively remove *edges* in the miRNA-p53 network, using a first-of-a-kind CRISPR-based screen. We demonstrate that removing edges sheds new light on pathways, in ways not achievable through node-based approaches, which may lead to novel and non-obvious therapeutic opportunities.

2.4 Materials and Methods

2.4.1 Preparation of the CRISPR plasmid library

The CRISPR plasmid library was prepared by following the lentiCRISPRv2 cloning protocol provided by Dr. Feng Zhang (Department of Biology, MIT). Briefly, for each identified sgRNA target (20 nt), two oligos were synthesized. The first oligo was designed as 5'-CACCG-(20 nt sgRNA target sequence)-3'. The second oligo was designed as 5'-AAAC-(20 nt reverse complement of the sgRNA target sequence)-C-3'. All 93 pairs of oligonucleotides were synthesized by Sigma-Aldrich using its customized 96-well plate format (**Table A.9**). Each well contained the pair of oligos for a specific sgRNA target (100 nmol for each). The oligo pairs were reconstituted using 100 μ L of dH₂O. For annealing the oligo pairs, 2 μ L of each of the reconstituted oligo solutions was mixed with 2 μ L of 10X T4 DNA Ligase Buffer (New England Biolabs, catalog number: B0202S) and 16 μ L dH₂O. The mixtures were heated at 95°C for 4 minutes, then left at room temperature for 60 minutes. 1 μ g of the lentiCRISPRv2 plasmid (Addgene, catalog number: 52961) was digested with 1 μ L Esp3I (ThermoFisher Scientific, catalog number: ER0451) at 37°C for 1 hour and run out on an 1% agarose gel. The 12 kb band was extracted using the QIAquick Gel Extraction Kit (Qiagen, catalog number: 28704). 1 μ L of each of the annealed oligo pairs was mixed with 9,904 μ L dH₂O. Subsequently, 1 μ L of the oligo mixture was ligated with Esp3I-digested lentiCRISPRv2 using T4 DNA Ligase (New England Biolabs, catalog number: M0202S). To prepare the library, XL10-Gold Ultracompetent cells (Agilent, catalog number: 200314) were transformed and more than 300 individual clones were pooled. To confirm complexity, the library was subjected to Sanger sequencing (Genewiz) using primer P1 and analyzed using FinchTV (Geospiza).

2.4.2 General cloning protocols

Q5 High-Fidelity 2X Master Mix (New England Biolabs, catalog number: M0492) was used for all polymerase chain reactions (PCR) according to the manufacturer's protocol. All oligonucleotides were ordered from Sigma-Aldrich and are listed in **Table A.9**. Plasmids were constructed using PCR amplification, restriction digest (all restriction enzymes were ordered from New England Biolabs), and ligation with T4 DNA ligase (New England Biolabs, catalog number: M0202S). Gel purification and PCR purification were performed with QIAquick Gel Extraction (catalog number: 28704) and PCR Purification kits (catalog number: 28104) (Qiagen). Transformations were performed using NEB 5-alpha electrocompetent *Escherichia coli* (New England Biolabs, catalog number: C2987P). Minipreps were performed using QIAprep Spin Miniprep kit (Qiagen, catalog number: 27104). The final plasmids were confirmed by both restriction enzyme digestion and direct Sanger sequencing. To generate the Bcl-2 sgRNA a pair of oligonucleotides (Forward: 5'-CACCGAATCAGCTATTTACTGCCAA-3', Reverse: 5'-AAACTTGGCAGTAAATAGCTGATTC-3') was annealed and cloned into the Esp3I-treated lentiCRISPRv2 plasmid following the same procedure for the lentiviral library construction. The zeocin resistance gene/sgRNA1 and zeocin resistance gene/sgRNA2 sequences were prepared from two rounds of PCR. First, the fragments were PCR amplified from U6-BCL2/sgRNA-PEF1 using primers P12 and P13 or P14. Second, the final fragments were PCR amplified from the first round PCR products using primers P12 and P15. Subsequently, the PCR products were cloned into the U6-BCL2/sgRNA-PEF1 plasmid using KpnI and EcoRI sites.

2.4.3 Cell culture

HEK293 cells were acquired from American Type Culture Collection (ATCC, catalog number: CRL-1573). HCT116 wild-type and HCT 116 p53^{-/-} cells were gifts from Dr. Michael A. White (University of Texas Southwestern Medical Center). Flp-In-293 cells were purchased from ThermoFisher Scientific (catalog number: R75007). All cell lines were maintained at 37°C, 100% humidity and 5% CO₂. Cells were grown in Dulbecco's modified Eagle's medium (DMEM, Invitrogen, catalog number: 11965–1181) supplemented with 10% fetal bovine serum (FBS, Invitrogen, catalog number: 26140), 0.1 mM MEM non-essential amino acids (Invitrogen, catalog number: 11140–050), and 0.045 units/mL of penicillin and 0.045 units/mL of streptomycin (Invitrogen, catalog number: 15140). In addition, 100 µg/mL zeocin (ThermoFisher Scientific, catalog number: R25001) was used for maintaining the Flp-In-293 cells. To pass the cells, adherent cultures were first washed with Dulbecco's phosphate-buffered saline (PBS, Mediatech, catalog number: 21-030-CM), then trypsinized with Trypsin-EDTA (0.25% Trypsin with EDTAX4Na, Invitrogen, catalog number: 25200) and finally diluted in fresh medium.

2.4.4 Transient transfection

For transient transfection of miRNA mimics, 200 µL of DMEM was mixed with 25 nM (final concentration) of miR-34a mimic (Qiagen, catalog number: MSY0000255) or miR-cel-67 mimic (Dharmacon, catalog number: CN-001000-01), in addition to 2 µL of RNAiMAX (Invitrogen, catalog number: 13778030). The mixture was added to each well of 12-well culture treated plastic plates (Greiner Bio-One, catalog number: 665180) and incubated at room temperature for 20

minutes. Adherent cell cultures were washed with PBS, then trypsinized with Trypsin-EDTA and finally diluted in fresh medium to the cell density of 200,000 cells/800 μ L medium. 800 μ L of the diluted cell suspension was then added to the well containing the miRNA-RNAiMAX complex.

2.4.5 Generation of the CRISPR lentiviral screen library

To generate the lentiviral vectors, HEK293T cells were grown to 50–70% confluence and then transfected with 3.3 μ g of the CRISPR plasmid library, 3.3 μ g of the pMD2-VSVG plasmid, and 3.3 μ g of the psPAX2 plasmid using 20 mL of JetPRIME (Polyplus, catalog number: 114-01). 24 h later, the medium was removed and replenished with 5 mL of complete growth medium. In the next 3 days, the growth medium containing lentiviral vectors was harvested, and 5 mL of fresh complete growth medium was replenished. The final pooled 15 mL growth medium was centrifuged at 3,000 rpm for 15 min at 4°C to remove cell debris. The supernatant was filtered through a 0.45 μ m filter, dispensed into 1–2 mL aliquots and stored at -80°C. Viral titers were determined using qPCR Lentivirus Titration Kit (ABMGood, catalog number: LV900) following manufacturer's instructions. Briefly, 2 μ L of viral stock was mixed with 18 μ L of Virus Lysis Buffer and incubated at room temperature for 3 minutes. This viral lysate, together with positive control (STD1), positive control (STD2), and negative control (NTC), were subjected to qRT-PCR. Finally, the titer of the viral stock was calculated based on the formula provided by the manufacturer and determined to be 2.07×10^7 IU/mL. To generate the LIB-WT and LIB-p53^{-/-} stable cells, ~10 million cells were seeded onto a 10 cm petri dish. 16 hours later, cells were transduced using the lentiviral vectors at a multiplicity of infection (MOI) of 0.3. 48 hours post-transduction, cells were treated with 0.5 μ g/mL of puromycin (ThermoFisher Scientific, catalog

number: A1113802). Polyclonal stable cell line libraries were established after ~2 weeks of drug selection.

2.4.6 Sanger amplicon sequencing

To confirm the complexity of the LIB-WT and LIB-p53^{-/-} cell line libraries, total genomic DNA was isolated from LIB-WT and LIB-p53^{-/-} cells using the DNeasy Blood & Tissue Kit (Qiagen, catalog number: 69504). The cDNA fragments harboring the sgRNA target sequences were PCR amplified by using ~100 ng of the genomic DNA and primers P2 and P3. PCR conditions were one cycle of 30 seconds at 98°C, 40 cycles of 10 seconds at 98°C, 30 seconds at 60°C, and 30 seconds at 72°C. The 181 bp product was then subjected to direct Sanger sequencing using primer P2 and analyzed using FinchTV (Geospiza). To determine editing efficiency, total genomic DNA was isolated from BCL2tgt-WT and BCL2tgt-p53^{-/-} cells using the DNeasy Blood & Tissue Kit (Qiagen, catalog number: 69504). cDNA fragments harboring the miR-34a target site within the 3'UTR of BCL2 were PCR amplified by using ~100 ng of genomic DNA and primers P8 and P9. The 191 bp product was then subjected to direct Sanger sequencing using primer P9 and analyzed using FinchTV (Geospiza).

2.4.7 Next generation sequencing

To determine the relative abundance of the 93 sgRNA target sequences before and after the CRISPR screen, total genomic DNA was isolated from miR-34a-treated LIB-WT and LIB-p53^{-/-} cells at days 0 and 6 using the DNeasy Blood & Tissue Kit (Qiagen, catalog number: 69504).

cDNA fragments harboring the sgRNA target sequences were PCR amplified by using ~100 ng of the genomic DNA and primers P10 and P11, which added the 5'-overhang adapter sequence (5'-TCGTCGGCAGCGTCAGATGTGTATAAGAGACAG-3') and the 3'-overhang adapter sequence (5'-GTCTCGTGGGCTCGGAGATGTGTATAAGAGACAG-3') for subsequent Illumina NGS amplicon sequencing, which was performed at the Genome Sequencing Facility (GSF) at The University of Texas Health Science Center at San Antonio (UTHSCSA). To determine the editing efficacies of the BCL2 targets in the BCL2^{tg}-WT and BCL2^{tg}-p53^{-/-} cells, total genomic DNA was isolated using the DNeasy Blood & Tissue Kit. cDNA fragments harboring the miR-34a target site within the 3'-UTR of BCL2 gene were PCR amplified by using ~100 ng of the genomic DNA and primers P16 and P17, and subsequently subjected to Illumina NGS amplicon sequencing, with ~2 million reads generated for each sample. The relative abundances of all 93 sgRNA target sequences were calculated and represented as counts per million reads (CPM). Log-transformed values were used for presentation.

2.4.8 Next generation sequencing data analysis

Four genomic DNA samples (LIB-WT-D0, LIB-WT-D6, LIB-p53^{-/-}-D0, LIB-p53^{-/-}-D6) were subjected to the NGS amplicon sequencing. ~2 million individual reads were generated for each sample. Next, the 20-nt sgRNA sequences were extracted and matched to the 93 designed sgRNA sequences (valid reads) using the script NGS_processing.py. For all 4 samples, the valid reads account for more than 90% of the total reads. Next, the relative abundances of the 93 sgRNA targets were calculated by dividing the number of the reads matching a specific sgRNA target by the number of the total valid reads (**Table A.6**). Subsequently, for each sgRNA target

sequence, the normalized \log_2 (transformed counts per million reads) were calculated by evaluating \log_2 (relative abundance of a specific sgRNA target sequence * 1,000,000 + 1), which was shown in **Table A.7**. Finally, the cell line samples without miR-34a treatment (LIB-WT-D0 and LIB-p53^{-/-}-D0) were used as normalization controls and the normalized fold change for a specific sgRNA between day 6 (D6) and day 0 (D0) was calculated by evaluating $2^{(\text{normalized } \log_2(\text{transformed counts per million reads of day 6}) - \text{normalized } \log_2(\text{transformed counts per million reads of day 0}))}$, which was shown in **Table A.8**. To examine the indels generated within the 3'-UTR of the BCL2 gene in BCL2tgt-WT and BCL2tgt-p53^{-/-} cells, the top 10 most frequently detected sequences were extracted and aligned (**Figure A.7**).

2.4.9 Apoptosis assay

To determine the non-apoptotic cell population 72 hours post-transfection with 25nM of miR-34a mimic, 1 mL of the original cell growth medium was transferred into a 15 mL conical tube. Cells were washed with 1 mL of PBS solution, which was also collected. Cells were trypsinized using 150 μ L of trypsin-EDTA for 5 minutes at 37°C. Subsequently, the trypsin-EDTA was neutralized using 2 mL of the original cell growth medium/PBS washing solution mixture. The cells were harvested by centrifugation at 1,000 rpm for 5 minutes. The cell pellet was then re-suspended in 1 mL PBS solution, then subjected to centrifugation at 1,000 rpm for 5 minutes. Apoptosis was quantified using the Dead Cell Apoptosis Kit with Annexin V Alexa Fluor™ 488 & Propidium Iodide (PI) (Invitrogen, catalog # V13241), following manufacturer's instructions. Briefly, the harvested cell pellets were re-suspended in 100 μ L of 1X annexin-binding buffer before being stained with 1 μ L propidium iodide (100 μ g/ μ L) and 5 μ L of stock annexin V,

Alexa Fluor™ 488 conjugate for 15 minutes in the dark. Stained cells were then diluted with 400 µL of 1X annexin-binding buffer before subjected to flow cytometry. Excitation/emission wavelengths for the annexin V, Alexa Fluor™ 488 conjugate are 495/519 nm; for propidium iodide they are 533/617 nm.

2.4.10 Cell viability assay

Approximately 150,000 of the HEK293, Flp-In-293, FLP-EDIT1 and FLP-EDIT2 cells were seeded into 6-well plates in 2 mL of complete medium. FLP-EDIT1 and FLP-EDIT2 cells were maintained with 0.5 µg/mL puromycin. All cells were treated with 100 µg/mL zeocin. For each cell type, 6 wells were included so that one of the wells could be harvested and counted on each day (from day 1 to day 6 after seeding). Three independent experiments were performed. For live cell counting, the cell suspension was mixed with 0.4% Trypan Blue solution (Invitrogen, catalog number: 15250) at a 1:1 ratio (volume:volume). Unstained, live cells were then counted using a hemocytometer (Hausser Scientific, catalog number: UX-79001-00) under a light microscope.

2.4.11 Quantitative reverse transcription-PCR (qRT-PCR)

For measurement of BCL2 mRNA levels, total RNA was extracted using the RNeasy Mini Kit (Qiagen, #74104) 48 hours post-transfection. First strand synthesis was performed using the QuantiTect Reverse Transcription Kit (Qiagen, #205311). Quantitative PCR was performed using the KAPA SYBR FAST Universal qPCR Kit (KAPABiosystems, #KK4601), with

GAPDH levels used for normalization. Quantitative analysis was performed using the $2^{-\Delta\Delta Ct}$ method. Fold-change values are reported as mean with standard deviation. Primers used for BCL2 were (P4) 5'-CATGCTGGGGCCGTACAG-3' and (P5) 5'-GAACCGGCACCTGCACAC-3'. Primers used for GAPDH were (P6) 5'-AATCCCATCACCATCTTCCA-3' and (P7) 5'-TGGACTCCACGACGTACTCA-3'.

2.5 Results

2.5.1 CRISPR-based screen for microRNA target editing

We focus on five miRNAs – miR-34a, miR-145, miR-192, miR-194 and miR-215 – which are known to be directly or indirectly regulated by p53, and play elaborate roles in the p53 pathway (Navarro and Lieberman 2015; Sundaram et al. 2011; Feng et al. 2011). The target genes for each miRNA were compiled from miRTarBase (Chou et al. 2016). We selected targets that have been experimentally validated by multiple methods, including luciferase reporter assay, western blot, and quantitative RT-PCR (qRT-PCR) (**Tables A1-A5**). For each of the target genes, the miRNA target sites within its 3'UTR were determined using TargetScan (Agarwal et al. 2015). In total, 93 miRNA target sites were identified across the 71 target genes. The miRNAs and the 71 target genes are the nodes of the derived network, while the experimentally verified and high-confidence predicted interactions between the nodes, including interactions between miRNAs and target genes and between target genes themselves, are the network edges (**Figure 2.1a**). To selectively edit these edges, we employed SpCas9-mediated NHEJ, which typically introduces short insertions or deletions (indels) near its cutting site, and designed sgRNAs in which a PAM

is adjacent to the miRNA target seed sequence(s) in the 3'UTR (David P Bartel 2009) (**Tables A1-A5**).

Next, we constructed a pooled CRISPR sgRNA library, containing both SpCas9 and sgRNA expression cassettes (Sanjana, Shalem, and Zhang 2014). Equimolar amounts of the 93 pairs of oligonucleotides were mixed and cloned into a lentiviral vector (lentiCRISPRv2). To confirm library complexity, we sequenced the resulting plasmid library. The resulting reads displayed consistent flanks with a 20-bp “noisy” sgRNA target sequence, matching the expected pattern from the sgRNA mixture (**Figure A.1**). Subsequently, the lentiviral library was used to infect HCT116 wild-type (WT) and HCT116 p53^{-/-} cells at a multiplicity of infection (MOI) of 0.3, which has been shown (Shalem et al. 2014) to yield at most one integration of the sgRNA cassette in the majority of cells (**Figure 2.1b**). To verify the complexity of our resulting libraries in cells (named LIB-WT and LIB-p53^{-/-}) was maintained, the sgRNA locations were amplified from genomic DNA and subjected to Sanger sequencing, which again displayed the expected pattern (**Figure A.2**).

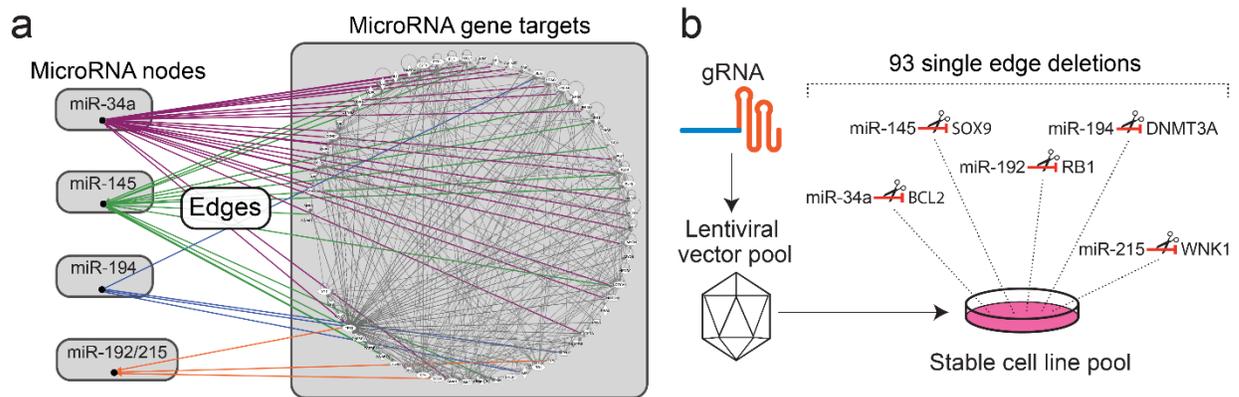

Figure 2.1: p53-miRNA network and CRISPR-based edge screens. (a) Complexity of the p53-miRNA network with nodes comprising the indicated miRNAs and their 71 target genes (detailed list provided in Table A.1-A.5) and edges based on experimentally verified and high-confidence predicted direct interactions, derived using Qiagen Ingenuity Pathway Analysis. (b) CRISPR-based lentiviral libraries were prepared using the lentiCRISPRv2 system. The stably integrated CRISPR sgRNA constructs were recovered by PCR and the sgRNA targets were identified using NGS.

In parallel, to test the efficacy of the viral system, we prepared two CRISPR lentiviral vectors that target the open reading frame (ORF) of the zeocin resistance gene (target 1: 5'-TCGCCGAGCGGTCGAGTTC-TGG; target 2: 5'-CTCACCGCGCGACGTCGC-CGG; PAM underlined), and stably integrated them into cell line Flp-In-293 (ThermoFisher Scientific) which harbors the zeocin resistance gene. As shown in **Figure A.3**, disruption of the zeocin resistance gene abolished resistance to zeocin (100 $\mu\text{g}/\text{mL}$) in the two resulting cell lines (FLP-EDIT1 and FLP-EDIT2), compared to the parental Flp-In-293 cells.

Using the established cell lines (LIB-WT and LIB-p53^{-/-}), we focused on the role of miR-34a in the overall p53-miRNA network (**Figure 2.1a**). miR-34a is transcriptionally activated by p53 and induces an anti-proliferative phenotype including senescence, cell cycle arrest at the G₁ phase, and apoptosis (Chang et al. 2007; Bader 2012). In turn, over-expression of miR-34a

increases p53 protein level and stability (Navarro and Lieberman 2015). Importantly, our established cell lines (LIB-WT and LIB-p53^{-/-}) do not produce miR-34a (**Figure A.4**), and can therefore be considered to lack the miR-34a node. The miR-34a targets and target sites are still present, however, and therefore the addition of miR-34a to these cells re-establishes the miR-34a network. Compared to baseline miR-34a expression there is a 71-fold increase in mature miR-34a levels 48 hours post-transfection.

We adopted a growth competition assay mediated by ectopic exposure to miR-34a mimics. miRNA mimics are chemically synthesized double-stranded RNA molecules that when transfected into a cell behave similar to a mature endogenous miRNA, regulating the same mRNA (and non-mRNA) targets through the same interactions as the endogenous miRNAs. We treated both cell lines (LIB-WT and LIB-p53^{-/-}) to 25 nM of miR-34a mimic for 6 days. Cells were harvested at day 0 (before miRNA mimic transfection) and at day 6. For each sample, sgRNA constructs were amplified from genomic DNA and subjected to NGS amplicon sequencing to assess the relative abundance for each of the 93 sgRNA target sequences (**Tables A.6-A.7**). The most enriched or depleted sgRNA targets, defined by fold-changes between day 6 and day 0 larger than 10, were identified for both LIB-WT and LIB-p53^{-/-} cells (**Figure 2.2, Table A.8**).

Intriguingly, RBX1 (RING-box protein 1), a RING subunit of SCF (Skp1, Cullins, F-box) E3 ubiquitin ligases, was highly enriched in both cell lines. Although not a direct target of miR-34a, over-expression of RBX1 has been demonstrated to increase cancer cell survival (Jia and Sun

2009), and thus could serve as a general response mechanism to cellular stress induced by ectopic miR-34a. Additionally, for a subset of gene targets, we observed differential response to miR-34a mimic between the LIB-WT and LIB-p53^{-/-} cells (**Table A.8**). For example, the sgRNA targeting the anti-apoptotic gene BCL2 was enriched in the LIB-p53^{-/-} cells after miR-34a mimic transfection while no enrichment was observed in the LIB-WT cells (**Table A.9**).

2.5.2 Node perturbations versus edge edits in biological networks

Our edge editing approach revealed (**Figure 2.2a**) several clones that are enriched or depleted after prolonged exposure to ectopic miR-34a. To assess the impact of edge removal (through ablation of miRNA:target interactions) we focused on BCL2, a gene that shows differential expression in response to miR-34a treatment between the two cell lines (**Figure 2.2b**) and is known to be involved in cell survival (Cory and Adams 2002).

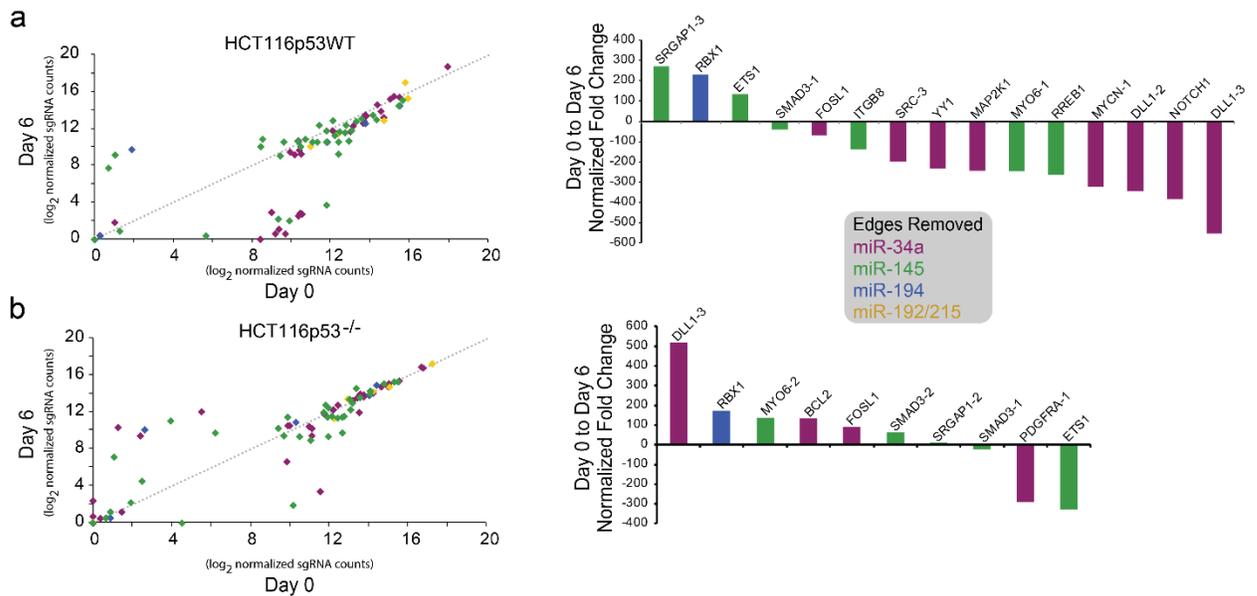

Figure 2.2: High-throughput editing of edges with CRISPR libraries in (a) HCT116p53WT (LIB-WT) and (b) HCT116p53^{-/-} (LIB-p53^{-/-}) cells. The sgRNA targets showing the highest fold changes (> 10) after 6 days treatment of 25nM with miR-34a mimic are shown, with values indicating enrichment and negative values indicating depletion.

Returning to the HCT116 wild-type (WT) and HCT116 p53^{-/-} cells, we removed the miR-34a target site from the BCL2 locus. We prepared a single sgRNA construct designed against the BCL2 3'UTR and established stable cell lines (BCL2^{tgt}-WT and BCL2^{tgt}-p53^{-/-}) using the same viral delivery system. Sanger and NGS sequencings of PCR products spanning the sgRNA target site showed that edits (indels) occurred immediately upstream of the PAM (**Figure A.6-A.7**) in both cell lines. Additionally, we compared the sgRNA sequence targeting BCL2 (5'-AATCAGCTATTTACTGCCAAAGG-3', **Table A.1**) against the human genome, confirming BCL2 as the unique target and indicating that non-specific targeting by this sgRNA should be minimal.

Treating delivery of ectopic miR-34a mimic as perturbation of a network node and removal of the miR-34a/BCL2 interaction as perturbation of a network edge (**Figure 2.3a**), there are four possible combinations (node and edge present/absent). When miR-34a levels are low (i.e., the node is absent) the presence or absence of the edge does not impact survival (**Figure A.8**) of either cell line.

In the context of node perturbation, the introduction of ectopic miR-34a in wild-type cells induces apoptosis (**Figure 2.3b right panel** and **Figure A.9**; cell viability is 87.6% without the miR-34a node, and 71.6% with the miR-34a node; $p = 0.006$). Similar changes were observed in p53^{-/-} cells (**Figure 2.3b left panel** and **Figure A.9**; cell viability is 86.1% without the miR-34a node, and 80.0% with the miR-34a node; $p = 0.002$). In this case, perturbing the miR-34a node results in the same behavior for both p53 wild-type and p53^{-/-} cells.

In the context of edge perturbation, the response of the cell lines to ectopic miR-34a is sensitive to the presence of the miR-34a/BCL2 edge. Specifically, removing the ability of miR-34a to regulate BCL2 in the p53^{-/-} cells induces apoptosis (**Figure 2.3b left panel** and **Figure A.9**; cell viability is 84.8% without the miR-34a/BCL2 edge, and 80.0% with the miR-34a/BCL2 edge; $p = 0.015$), while no such phenotypic changes are observed in p53 WT cells (**Figure 2.3b right panel** and **Figure A.9**; cell viability is 72.0% without the miR-34a/BCL2 edge, and 71.6% with the miR-34a/BCL2 edge; $p = 0.900$). We note that the same conclusions can be drawn when quantifying the early- or late-apoptotic cells (**Figure A.10**).

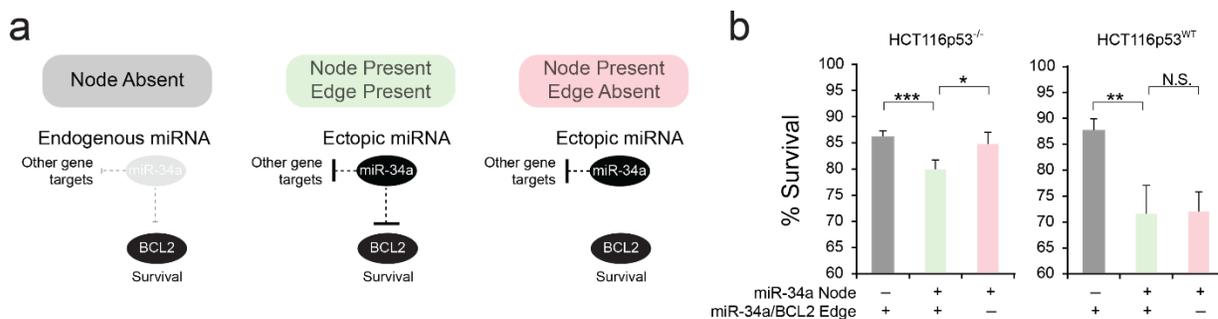

Figure 2.3: Growth competition analysis after ectopic miR-34a delivery using node vs. edge approaches. (a) Schematic illustration of node vs. edge analysis. Ectopic miR-34a represents a network node and the miR-34a/BCL2 interaction represents a network edge. (b) The node-based approach shows that addition of the miR-34a node induces apoptosis in both p53 WT and deficient cells. In contrast, the edge-based approach reveals that introduction of the miR-34a/BCL2 edge induces apoptosis only in the p53-deficient cells and not in p53-WT cells.

To further explore the response to miR-34a in BCL2_{tgt}-WT cells, we quantified expression of the BCL2 mRNA in response to miR-34a mimics using qRT-PCR. As expected, miR-34a suppresses the expression of BCL2 mRNA in the WT and p53^{-/-} cells by 55% and 40%, respectively (**Figure A.11**). In the BCL2_{tgt}-p53^{-/-} cells, ectopic miR-34a has a minimal effect on BCL2 mRNA level (95% compared to the control-treated sample; $p = 0.71$). In the BCL2_{tgt}-WT cells, ectopic miR-34a results in a significant down-regulation of BCL2 expression (62% compared to the control-treated sample; $p = 0.028$), possibly due to additional p53-miR-34a regulatory mechanisms.

2.6 Discussion

Biological networks consist of nodes and the interactions between them (edges). Conventional screening methods remove one node at a time, disrupting all edges connected to that node, and therefore producing a relatively blunt effect. An inhibitor that perturbs or removes a single

node yields diverse and systemic changes in the whole network through both direct and indirect connections (Kang et al. 2015), which may explain the heterogeneity observed with single-molecule associated therapeutics.

Our approach reveals edge-specific effects related to the pro-apoptotic p53 and anti-apoptotic Bcl-2 proteins, focal nodes of apoptotic signaling. Normally, p53-dependent inhibition of Bcl-2 and induction of BAX, PUMA and NOXA overcome the anti-apoptotic threshold set by Bcl-2 family members. Conceivably, the difference in apoptosis observed between the BCL2tgt-WT and BCL2tgt-p53^{-/-} cells treated with miR-34a mimics (**Figure 2.3b**) may be explained by the presence of wild type p53-dependent upregulation of PUMA or NOXA in p53 WT cells and not in p53^{-/-} cells. Additionally, p53 could disrupt the binding of POU4F1 (POU Class 4 Homeobox 1) to the promoter of BCL2 and thus indirectly down-regulate BCL2 expression (**Figure A.11**).

CHAPTER 3

IMPACT OF VARIABILITY IN CELL CYCLE PERIODICITY ON CELL POPULATION DYNAMICS

3.1 Author contributions

This work was completed alongside Tyler Quarton (TQ) and Leonidas Bleris (LB). Chance Nowak (CN) performed the experiments. CN, TQ, and LB analyzed the data and developed the models. CN, TQ, and LB wrote the manuscript. LB supervised the project.

3.2 Abstract

The cell cycle consists of a series of orchestrated events controlled by molecular sensing and feedback networks that ultimately drive the duplication of total DNA and the subsequent division of a single parent cell into two daughter cells. The ability to block the cell cycle and synchronize cells within the same phase has helped understand factors that control cell cycle and the properties of each individual phase. Intriguingly, when cells are released from a synchronized state, they do not maintain synchronized cell division and rapidly become asynchronous. The rate and factors that control cellular desynchronization remain largely unknown. In this study, using a combination of experiments and simulations, we investigate the desynchronization properties in cervical cancer cells (HeLa) starting from the G_1/S boundary following double-thymidine block. Propidium iodide (PI) DNA staining was used to perform flow cytometry cell cycle analysis at regular intervals of 8 hours, and a custom auto-similarity function to assess the desynchronization and quantify the convergence to asynchronous state. In parallel, we developed

a single-cell phenomenological model that returns the DNA concentration across the cell cycle stages and fitted the parameters using experimental data. Simulations of population of cells reveal that the cell cycle desynchronization rate is primarily sensitive to the variability of cell cycle duration within a population. To validate the model prediction, we introduced lipopolysaccharide (LPS) to increase cell cycle noise. Indeed, we observed an increase in cell cycle variability under LPS stimulation in HeLa cells, accompanied with an enhanced rate of cell cycle desynchronization. Our results show that the desynchronization rate of artificially synchronized in-phase cell populations can be used as a proxy of the degree of variance in cell cycle periodicity, an underexplored axis in cell cycle research.

3.3 Introduction

Cell division is traditionally described as a general process divided into two phases, the interphase and mitosis (cell division). Interphase is further divided into three subphases; Gap 1 phase (G_1) in which the cell has a DNA content of $2N$, synthesis phase (S) in which the cell's DNA content is greater than $2N$ but less than $4N$, and Gap 2 phase (G_2) in which the cell's DNA content is $4N$ upon completion of synthesis. Early observations into cell cycle progression showed that the timing of G_1 phase is highly variable not just between cell types but also between cells within a monoclonal population, and that this variable length directly impacts the heterogeneity observed in clonal populations for cell cycle periodicity (Smith and Martin 1973; Prescott 1968). Additionally, a critical point in the cell cycle was discovered (Temin 1971), in which cells were found to be committed to DNA synthesis independent of environmental factors. Moreover, it was later demonstrated that under various suboptimal nutritional conditions, cell

cycle progression could be arrested at the G₁/S boundary, and escapement into S-phase could only occur once suitable nutritional needs were restored (Pardee 1974). The boundary was termed the restriction point (R-point), whereby cells could enter a lower metabolic rate (a quiescent state) to remain viable until adequate nutrition is restored allowing the necessary constituents to be present in suitable amount to enable DNA synthesis (Pardee 1974). Ultimately, it was shown that the high variability of G₁ phase duration can be attributed to a cell's ability to overcome the restriction point (Zetterberg and Larsson 1985).

Investigations into cell cycle progression and regulation often start with the need to synchronize cells within a population to the same cell cycle phase (Schorl and Sedivy 2007; PK, A, and SF 2001). One common approach to cell cycle synchronization is the double-thymidine block that interferes with nucleotide metabolism resulting in an inability of the cells to synthesize DNA causing a cell cycle arrest at the G₁/S boundary (Bjursell and Reichard 1973; G. Chen and Deng 2018). Interestingly, when synchronized cell populations are released from cell cycle arrest, they quickly desynchronize, and reach a state of “asynchronicity,” whereby the individual cell cycle phases stabilize into fixed percentages within the overall population. Indeed, simply sampling cells from an asynchronously growing *in vitro* cell culture will reveal (**Figure 3.1a**) the fixed percentages for the three phases of interphase (G₁, S, and G₂). Additionally, cells can be pulse-labeled with bromodeoxyuridine (BrdU) to create a semi-synchronous cell population in which only cells in actively progressing through S-phase incorporate the thymidine analog BrdU into their genome, and thus the original pulse-labeled population can be tracked overtime by using a fluorescently conjugated BrdU antibody (Chiorino et al. 2001). These observations again showed

that the initially pulse-labeled cells progressed synchronously through the cell cycle for some time before quickly desynchronizing and resorting back to an asynchronous DNA distribution profile.

The inherent variability of cell cycle duration between identical cells may be accounted for by considering sources of cellular noise. In other words, the variability between cellular constituents such as signaling and transcriptional factors, along with the biochemical stochasticity of molecular interactions do likely propagate to the phenotypic level and may be responsible for varying timing events that dictate cell cycle progression. For example, signalling factors in a tumor microenvironment that confer a higher degree of intercell variability contribute to tumor cell heterogeneity and pathology (Nguyen et al. 2016; O’Duibhir et al. 2014). Therefore, it is important to examine the implications of cellular noise to cell cycle periodicity.

In this report, we investigated the rate of cell cycle desynchronization by measuring the change in the DNA distribution of a population of cells over time. To this end, we measured the single-cell DNA concentration of a population of cells as they transition from an initial state of cell cycle synchrony, where cells are experimentally locked into the G_1/S boundary, to a state of asynchrony. We used statistical tools to quantify the dynamic change in the DNA probability density function over time from an initial synchronized cell population. Subsequently, we developed a mathematical model to simulate at single-cell level the DNA concentration as the cell transitions through cell cycle states, and finally, experimentally validated our model prediction. More specifically, our model revealed that cell cycle desynchronization rates were

particularly sensitive to the variability of cell cycle duration within a population. With this insight, to validate the results we introduced external noise in synchronized cells using lipopolysaccharide and, indeed, confirmed an increase in cell cycle desynchronization. Considering the ubiquitous role of the cell cycle properties to cell health, the implications of our work extend to numerous fronts.

3.4 Materials and Methods

3.4.1 Cell culturing and synchronization

HeLa cells were grown in Gibco DMEM supplemented with 10%FBS, 1X PenStrep, 2mM glutamine, and 1X Gibco NEAA and grown at 37°C with 5% CO₂. 50,000 cells were seeded per well in 6 well plates. 24 hours post-seeding cells were treated with 2mM of thymidine for 19 hours after which the cells were washed with 1X PBS and given fresh complete media to release from the first thymidine block. The cells then incubated for 9 hours before receiving a second dose of 2mM of thymidine for 15 hours. Cells were washed with 1X PBS to remove thymidine before given fresh media to continue to grow unimpeded. Cells harvested at t=0 were collected immediately following the second PBS wash. Additional wells were harvested every 8 hours for 88 hours. Asynchronous cells were harvested at same time as synchronized cells for each time point. Cells were harvested by washing with PBS, detached from the well with trypsin-EDTA (0.25%) for 3 min at 37°C then quenched with fresh complete media. Harvested cells were pelleted at 1000rpms for 5 min at room temperature. The supernatant was removed and the cell pellet was resuspended in 1X PBS, then pelleted again at 1000rpms for 5 min at room

temperature. The supernatant was removed and the cell pellet was resuspended in 1 mL of 70% ethanol and stored at 4°C for a minimum of 24 hours to fix the cells. LPS derived from *E. coli* 0E111 was reconstituted in PBS without Mg²⁺ or Ca²⁺ at a concentration of 1mg/mL. LPS solution was added directly to the cell culture media after replacing with fresh media initiating the release from the double thymidine arrested state.

3.4.2 Propidium iodide staining

After fixation, cells were pelleted by centrifuged at 1000 rpms for 5 minutes at room temperature. The fixing solution was aspirated off the cell pellet, and resuspended in 1X PBS. Cells were counted for each sample, and then normalized to the lowest cell count for uniform propidium iodide (PI) staining across samples. The PI staining procedure was done according to manufacturer's directions (Propidium Iodide Flow Cytometry Kit, cat# ab139418).

3.4.3 Cell cycle phase analysis

Stained cells were subjected flow cytometry using a BD LSRFortessa™ flow cytometer. PI fluorescence was excited with a 561nm laser and emission was detected using a 610/20 nm band-pass filter. Assignment of cell cycle phases were performed using the univariate modeling via the Dean-Jett-Fox algorithm with FlowJo 10.7.1.

3.4.4 Lentiviral HeLa transduction for H2B-FT expression

The fluorescent tracker sequence was obtained from addgene (#157671) and cloned using primers P1: gaagagttcttcagctcggtgac and P2: cagtaggggtaccccggaattagatcgatctctcgacatcc. The amplicon was digested with restriction enzymes BsiWI and KpnI and inserted into the LentiCRISPRv2 (addgene #52961) backbone. The resulting plasmid was transfected into HEK293T cells along with pMD-VSVG and psPAX2 plasmids to generate viral particles that are released into the media. The media was aspirated two days post-transfection, and replenished with 5 mL of fresh media every day for three days. The 15 mL of harvested viral-containing media was passed through a 0.45 μm filter and dispensed into 1 mL aliquots. 250 μl was used to transduce HeLa cells, and 0.5 $\mu\text{g}/\text{mL}$ of Puromycin was used to select for integrated clones for 7 days.

3.4.5 Time-lapse microscopy

Images were collected every 20 min for 72 hours using Hamamatsu camera attached to the Olympus IX81 microscope at 10x magnification. Cells were maintained at 37°C and 5% CO₂. The exposure time was 250 ms for Brightfield and 100ms for TexasRed using Chroma filter ET560/40x (excitation) and ET630/75m (emission).

3.4.6 Modeling and simulations

All models and simulations were developed and tested in Mathematica.

3.5 Results

3.5.1 Thymidine-based arrest and desynchronization

The exogenous introduction of excessive thymidine into cells interrupts DNA synthesis, arresting the population of cells in the G₁/S-phase transition. Upon release, the population of cells are permitted to reenter their respective cell cycles. Ultimately, the population of cells will become asynchronous with respect to their cell cycles, yielding a PI fluorescent profile. The PI distributions dynamically change as the population desynchronizes.

After cells were synchronized via double-thymidine block, timepoints were collected every 8 hours for a total of 88 hours. Both asynchronous (untreated) cells (**Figure 3.1b**) and synchronized (**Figure 3.1c**) were subjected propidium iodide staining and flow cytometry analysis. Notably, we observed near full synchronization of cells as judge by the first few timepoints (**Figure 3.1c**) in the synchronous population. While inhibition of DNA synthesis can cause replicative errors due to stalled replication forks, resulting in quiescence or cell death, we did not observe neither an increase in cell death nor any quiescent populations, which would manifest as a sub-G₁/G₁ population at timepoint 8. Each PI histogram was subjected to cell cycle phase classifier (Watson, Chambers, and Smith 1987; Fox 1980; Dean and Jett 1974) with the cell cycle phase distribution displayed as percentages of the total population. As we observe in **Figure 3.1d**, the synchronized population eventually reaches an asynchronous distribution. The residual plots of the DNA distribution of the synchronous population against the asynchronous population ultimately converges to within 8.4%, 1.5%, and 6.1% of G₁, S, and G₂, respectively (**Figure B.1**).

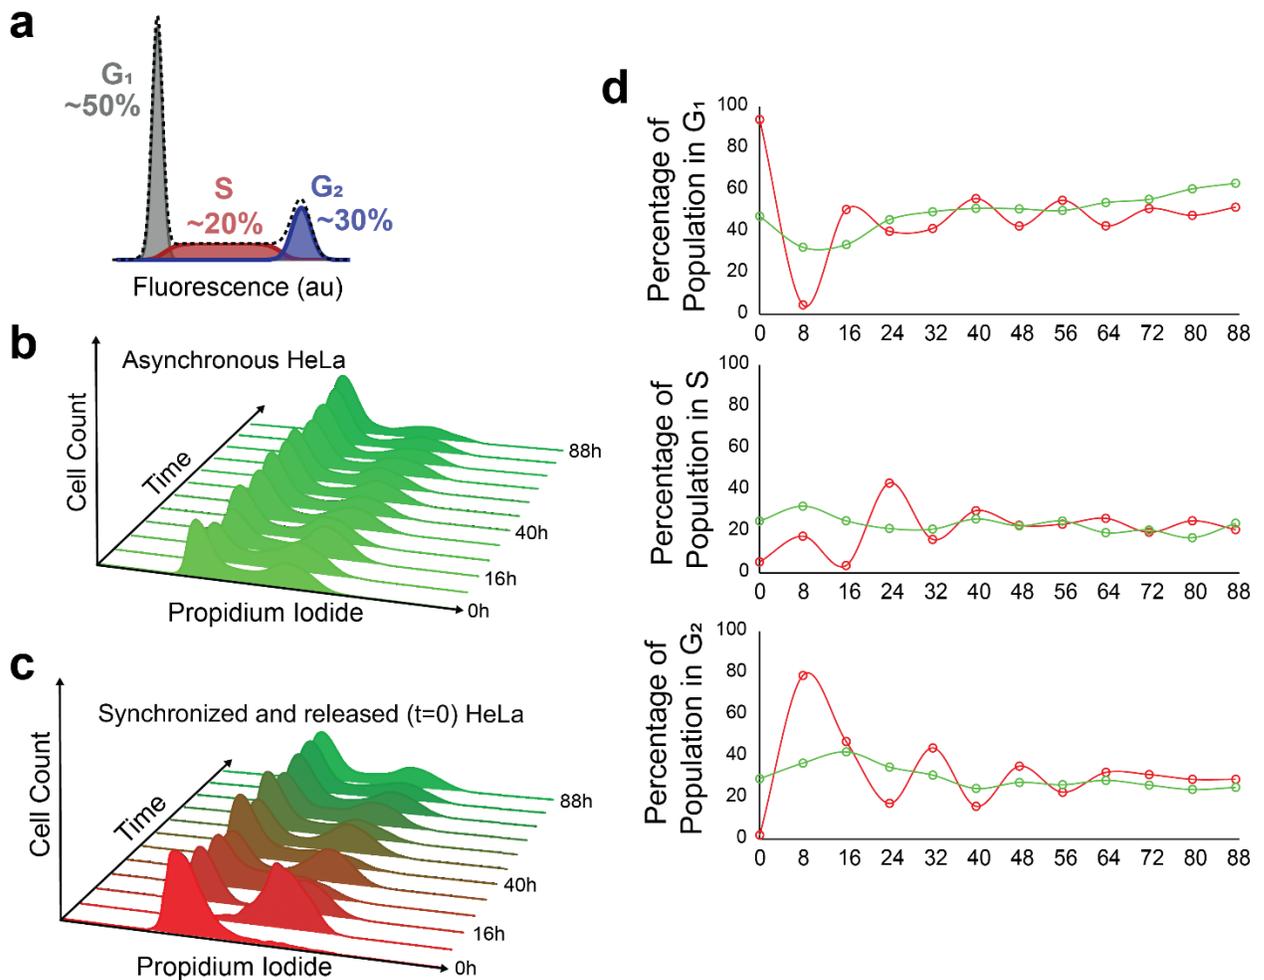

Figure 3.1: Cell cycle desynchronization via double thymidine block and release. a) Cell cycle phases as indicated by cell DNA content and approximate phase distribution in an asynchronous population. b) Fluorescent profile of propidium iodide (PI) stained cells during asynchronous growth from t=0 to t=88. c) Fluorescent profile of PI-stained cells following G₁/S synchronization by double thymidine block from t=0 to t=88. d) Percentages of cells in a given cell cycle phase at a given time point; asynchronous cell growth in green and desynchronous cell growth in red. The cell cycle phase percentages for each time point were determined via the Dean-Jett-Fox model.

3.5.2 Quantifying cell synchronicity

The DNA dynamics during interphase of a population of cells is defined by the population's collective distribution of its DNA at a given time. If all the cells within a population are undergoing interphase synchronously, time separated measurements of the population's DNA distribution will accordingly change in time. This would mean that the DNA distribution of a population of cells will be different for each time measurement. Conversely, if the population's cells are independently progressing through interphase, temporal differences between the population's DNA distribution become indistinguishable, rendering its DNA distribution into a static steady-state (**Figure 3.1a**).

With this in mind, we can create a set of assumptions: Let $\{\mathbf{X}_t\}$ denote sets of observations generated from an evolving probability distribution at any point in time t . We define the auto-similarity function (ASF) between times t_1 and t_2 as

$$\Sigma_{\mathbf{X}\mathbf{X}}(t_1, t_2) = \max_{-\infty < x < \infty} \left(F_{\mathbf{X}_{t_1}}(x) - F_{\mathbf{X}_{t_2}}(x) \right) + \max_{-\infty < x < \infty} \left(F_{\mathbf{X}_{t_2}}(x) - F_{\mathbf{X}_{t_1}}(x) \right)$$

where $F_{\mathbf{X}_t}$ denotes the cumulative distribution function of a given set of observations \mathbf{X}_t .

Essentially, the auto-similarity function is the Kuiper two-sample test statistic, which measures the similarity between two sets of data, performed on a single, time evolving variable \mathbf{X}_t rather than two distinct variables. The Kuiper test statistic is rotation-invariant, making its application insensitive to the “starting points” of the data to be compared. As the DNA content measured in our cell populations cycle between $2N$ to $4N$, the data collected from our cell cycle experiments

are inherently cyclical, making the use of a rotation-invariance test statistic ideal. If the evolving distribution eventually converges to a steady-state, we expect $\Sigma_{\mathbf{X}\mathbf{X}}(t_i, t_{i+1}) \rightarrow 0$ for some successive time measurements t_i and t_{i+1} as $t \rightarrow \infty$, where a value of 0 indicates full asynchrony. Conversely, we interpret non-zero, positive evaluations of the ASF to indicate dissimilarity, where, in the case of a cyclically evolving sets of data, evidence that the underlying probability distribution is in a transient state, where a maximum value of 1 indicates full synchrony (**Figures 3.2a**).

In our experiments, $\{\mathbf{X}_t\}$ is variable DNA fluorescently measured by flow cytometry in PI-stained populations of cells, where $t_i = \{0, 8, 16, \dots, 88\}$ indicates the hour corresponding to the i_{th} measurement of data collected with respect to their release from cycle arrest via double thymidine block at $t_0 = 0$. We expect that the ASF evaluation of times t_0 and t_1 to be the greatest as the population of cells synchronously progress through the cell cycle, resulting in markedly dissimilar distributions of DNA in observation sets \mathbf{X}_{t_0} and \mathbf{X}_{t_1} .

As the individual cells within a population variably progress through the cell cycle, we expect population DNA distributions to diverge, eventually settling to the classic asynchronous distribution profile (**Figure 3.1a-d**), where successive measurements of a no-longer-evolving variable are expected to be near-zero. We calculated the ASF between each temporally successive pair of data for both the synchronized cell population and the asynchronous control population (**Figure 3.2c**). We found that the ASF converges to a minimum of 0.127 from an initial value of 0.869, following a logistics curve. We observed an expected linear ASF from the

asynchronous population with slight oscillations, most likely emerging from unintended loss of mitotic cells during harvesting (mitotic shake off) positive slope (**Figure 3.2c**).

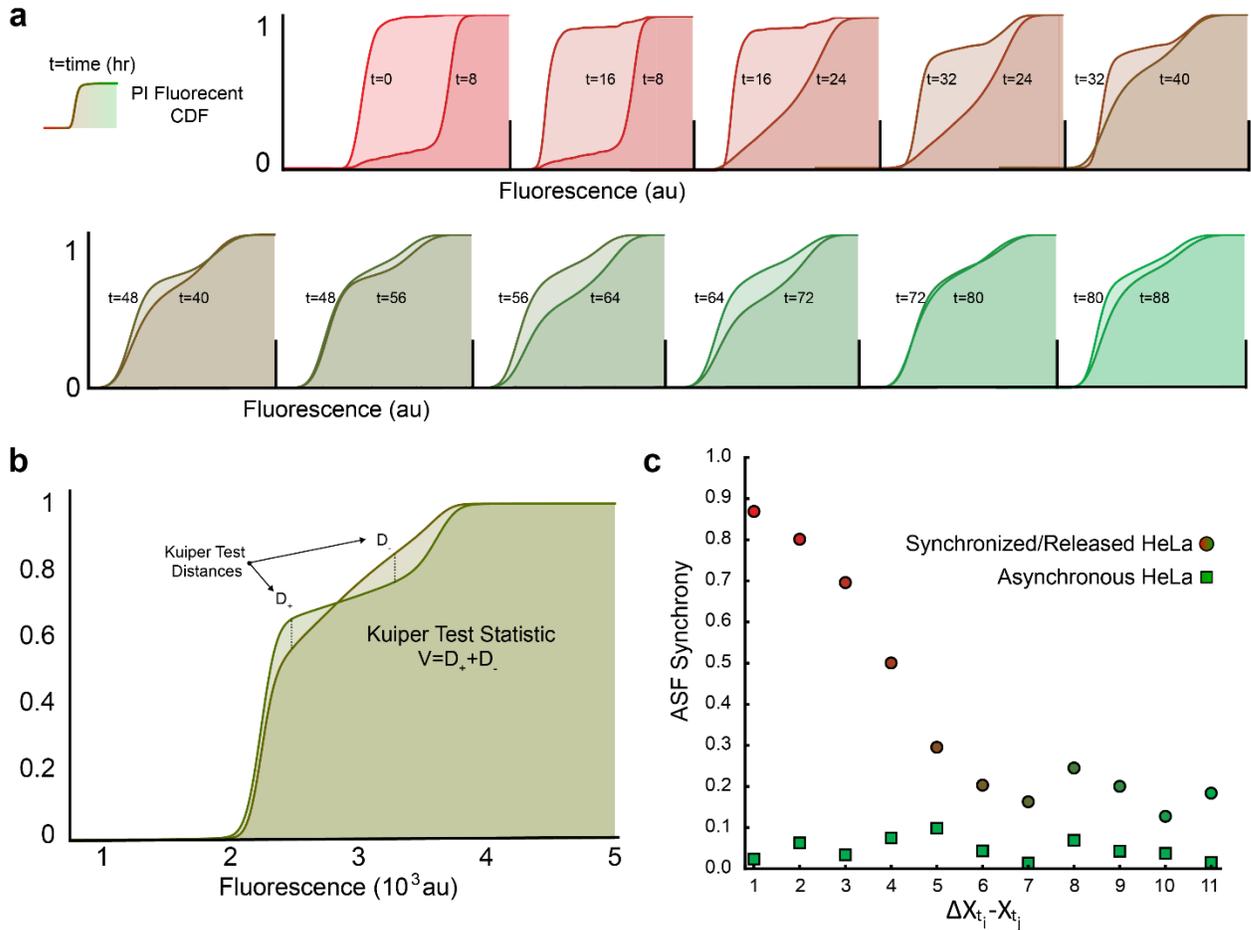

Figure 3.2: Rate of desynchronization using Kuiper Test Statistic. a) Pairwise comparison of PI CDFs for each time point (data shown is from synchronized cells). b) Visual representation of Kuiper Test Statistic determination between time points. c) Rate of desynchronization between asynchronous (green) and synchronized (red) Hela cells. Over time (~60 hours) synchronized cells being to reach an asynchronous state

3.5.3 A single cell interphase model

Cell cycle progression is intimately linked to a cell's dynamically changing DNA content.

Temporal transitions from a cell's state of $2N$ to $4N$ define cell cycle phases, where G_1 , S , and

G₂, correspond to genetic quantities of 2N, 2N⁺, and 4N, respectively, where the event of mitosis restarts the cell cycle for two progeny cells. Deterministically, we model a single cell's dynamic DNA content as

$$dna(t) = dna_0 + \frac{dna_{max} - dna_0}{1 + e^{-\beta(t-s)}} \quad t_0 \leq t \leq \tau$$

where dna_0 is the initial genetic content in phase G₁, dna_{max} is the maximum genetic content after synthesis, β parameterizes the synthesis rate, s is the time in which the cell is halfway through synthesis and determines the periods of G₁, S, and G₂, and t is time. We assume that synthesis faithfully duplicates the genetic content, where $dna_{max} = 2 dna_0$, thus reducing the above equation to:

$$dna(t) = dna_0 \left(1 + \frac{1}{1 + e^{-\beta(t-s)}} \right) \quad t_0 \leq t \leq \tau$$

We can further reduce Eq. 2 by representing β and s as functions of the cycle period τ as:

$$dna(t) = dna_0 \left(1 + \frac{1}{1 + e^{-24\left(t - \frac{2\tau}{3}\right)}} \right) \quad t_0 \leq t \leq \tau$$

where we assume that the duration of S is $\sim 1/3$ of the total cycle period. Accordingly, this single cell model captures DNA concentration during interphase using two parameters, the initial DNA concentration and the cell cycle period (**Figure 3.3a**).

To study the impact of the cell cycle period to the rate of asynchrony we use the Error-in-Variables (EIV) modeling approach to add noise to the cycle periodicity:

$$dna(t) = (dna_0 + \varepsilon_{dna_0}) \left(1 + \frac{1}{1 + e^{-24\left(t - \frac{2\tau + \varepsilon_\tau}{3}\right)}} \right) \quad t_0 \leq t \leq \tau$$

where $\varepsilon_\tau \sim N(0, \sigma_\tau^2)$ is a normally distributed error term with variance σ_τ^2 and $\varepsilon_{dna_0} \sim N(0, \sigma_{dna_0}^2)$ is additionally added to capture fluorescent variability seen as broadened peaks around G₁ and G₂ (**Figure 3.1a**). We simulate a population of 1,000 cells, each starting synchronously at G₁ with extrinsically varying initial DNA content and cell cycle periodicity, as they repetitively progress through interphase (**Figure 3.3b**). We then take temporal slices of the DNA content of the population of cells and plot the populations distribution of DNA content intermittently (**Figure 3.3b-c**). We finally apply ASF to the slices in a pairwise manner as done in the experiment (**Figure 3.2**). An observation from these simulations is that a Poisson distributed error term for variance, as opposed to normal distribution, did not accurately capture the DNA dynamics of desynchronized cells using our ASF analysis.

Importantly, we found that only by including a variance term to cell cycle periodicity were we able to capture population dynamics that recapitulates the experimental results. Moreover, our model revealed that increasing the magnitude of variance resulted in increasing rates of desynchronization (**Figure B.2**). In order to further evaluate our model's prediction, we sought to experimentally introduce an additional source of noise that might impact the overall variance of cell cycle duration.

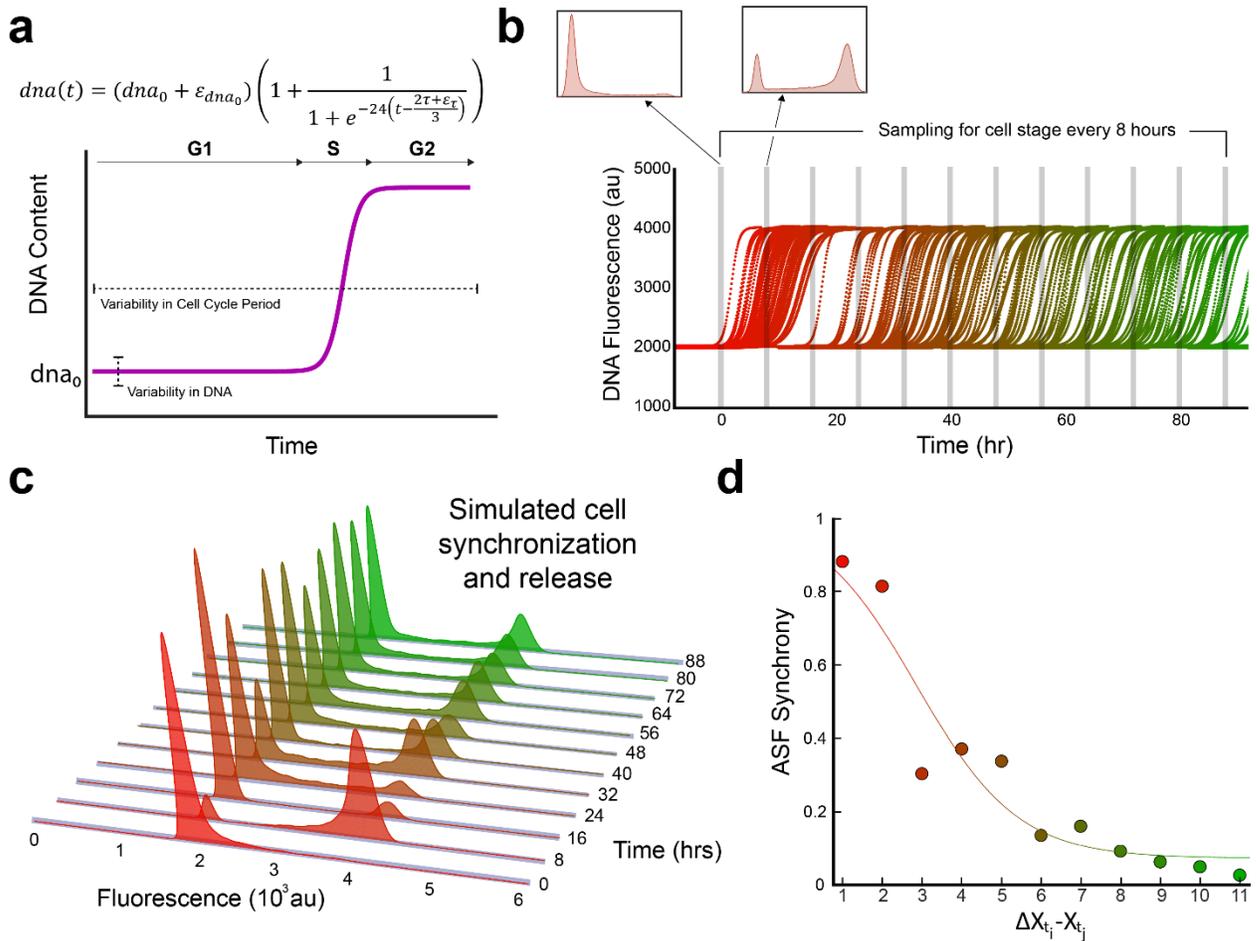

Figure 3.3: Single cell model of desynchronization. a) DNA synthesis is captured by the Gaussian error function where the relative durations of cycle phase are tunable. b) Cell cycle pace inheritance following a Gaussian distribution. c) Simulated data of PI staining of multiple lineages with normally distributed initial gene content. d) Desynchronization rate of simulated cell population.

3.5.4 Impact of LPS on cell cycle duration variability

Lipopolysaccharide (LPS) is a major component of the outer membrane of Gram-negative bacteria that can bind to TLR4 receptors initiating a signaling cascade that ultimately results in NF κ B translocation from the cytoplasm to the nucleus, where as a transcription factor, it initiates the upregulation of inflammation regulatory genes (Y. Wang et al. 2014; Savinova, Hoffmann,

and Ghosh 2009; N et al. 2017). Additionally, NF κ B activation can be induced by cytokines such as TNF α (Hayden and Ghosh 2014), which has been reported with contrasting roles, whereby NF κ B induction is associated with both the activation of pro-survival genes as well pro-apoptotic genes (R. E. C. Lee et al. 2016). In addition to regulating inflammation signaling pathways, NF κ B regulates major cell cycle regulatory factors (Bash, Zong, and G  linas 1997; Ankers et al. 2016; Ledoux and Perkins 2014; Kenter and Watson 1987). Interestingly, components of NF- κ B, such as RelA, have shown to interact with key cell cycle regulators, such as E2F transcription factors that are crucial in controlling progression through the G₁/S boundary (Ankers et al. 2016).

We therefore hypothesized that the contrasting nature of LPS stimulation in HeLa cells would result in a greater variance in overall cell cycle duration. Accordingly, if LPS is a viable approach for introducing cellular noise we would expect the desynchronization rate to increase compared to untreated synchronized cells (**Figure B.3**). Thus, in order to determine if LPS stimulation had any effect on cell cycle duration, we conducted a time-lapse experiment to track individual cells cell cycle duration. In order to have a better indication of relative position of each cell in relation to the cell cycle, we integrated a fluorescence tracker using lentiviral transduction that express the histone protein H2B fused to a fluorescent protein (H2B-FT) (Eastman et al. 2020). Upon expression, the H2B protein is incorporated into nucleosomes, which binds DNA, and therefore could more easily distinguish cells undergoing mitosis. Next, we treated asynchronously-growing HeLa cells with 1.0 μ g/mL of LPS derived from *E. coli* O111:B4, and monitored the duration of the cell cycle for individual cells with timelapse microscopy for 72 hours every 20 minutes (**Figure B.4**). We found that the overall variance was

higher in treated cells versus untreated cells with an accompanying increase in the mean duration 23.7 ± 4.73 and 21.7 ± 3.42 hours, respectively (**Figure 3.4a**). Additionally, we also found that the addition of LPS appeared to enhance cell motility, as LPS treated cells showed an increase in overall cell displacement (**Figure B.5**), which supports the notion that LPS can induce epithelial-mesenchymal transition via TLR4 signaling (Jing et al. 2012; H. Li et al. 2014; Cho et al. 2015).

We next sought to test if the predictability of our simulation model with the values obtained from the time-lapse microscopy would result in an increased desynchronization rate under LPS stimulation. In order to compare multiple synchronous cell samples, we normalized each sample to its initial ASF value ($\mathbf{X}_{t_0} - \mathbf{X}_{t_8}$, **Figure B.6**). Upon inputting our new values obtained from the time-lapse microscopy, our model indeed predicted an increase in desynchronization when treated with LPS compared to the untreated sample (**Figure 3.4b**).

Given that we were able to increase the variance of cell cycle duration with LPS, and that our simulation model predicted an increase in desynchronization due to increased cell cycle duration variance, we next tested if we could experimentally obtain higher rates of desynchronization using the previous approach of PI-staining time-separated synchronized cells. Therefore, we again synchronized HeLa cells via the double-thymidine block method, and immediately following release of the arrested cells, we treated with varying concentrations of LPS (0.0, 0.1, 0.5, 1.0 $\mu\text{g}/\text{mL}$) and collected timepoints every 8 hours for 88 hours. We then analyzed the PI-stained cell populations via FlowJo cell cycle classifier that uses the Dean-Jett-Fox algorithm, and while it was not able to detect substantial changes in the overall phase distributions at the

early timepoints (0-32 hours), the effects of LPS were more evident at the later timepoints (40-88 hours) (**Figure 3.4c**). Interestingly, our ASF analysis methodology (**Figure B.7-B.8**) was able to differentiate the impact on cell cycle desynchronization at all timepoints tested for all LPS concentrations, with each increase in LPS having a greater impact in cell cycle desynchronization (**Figure 3.4d**).

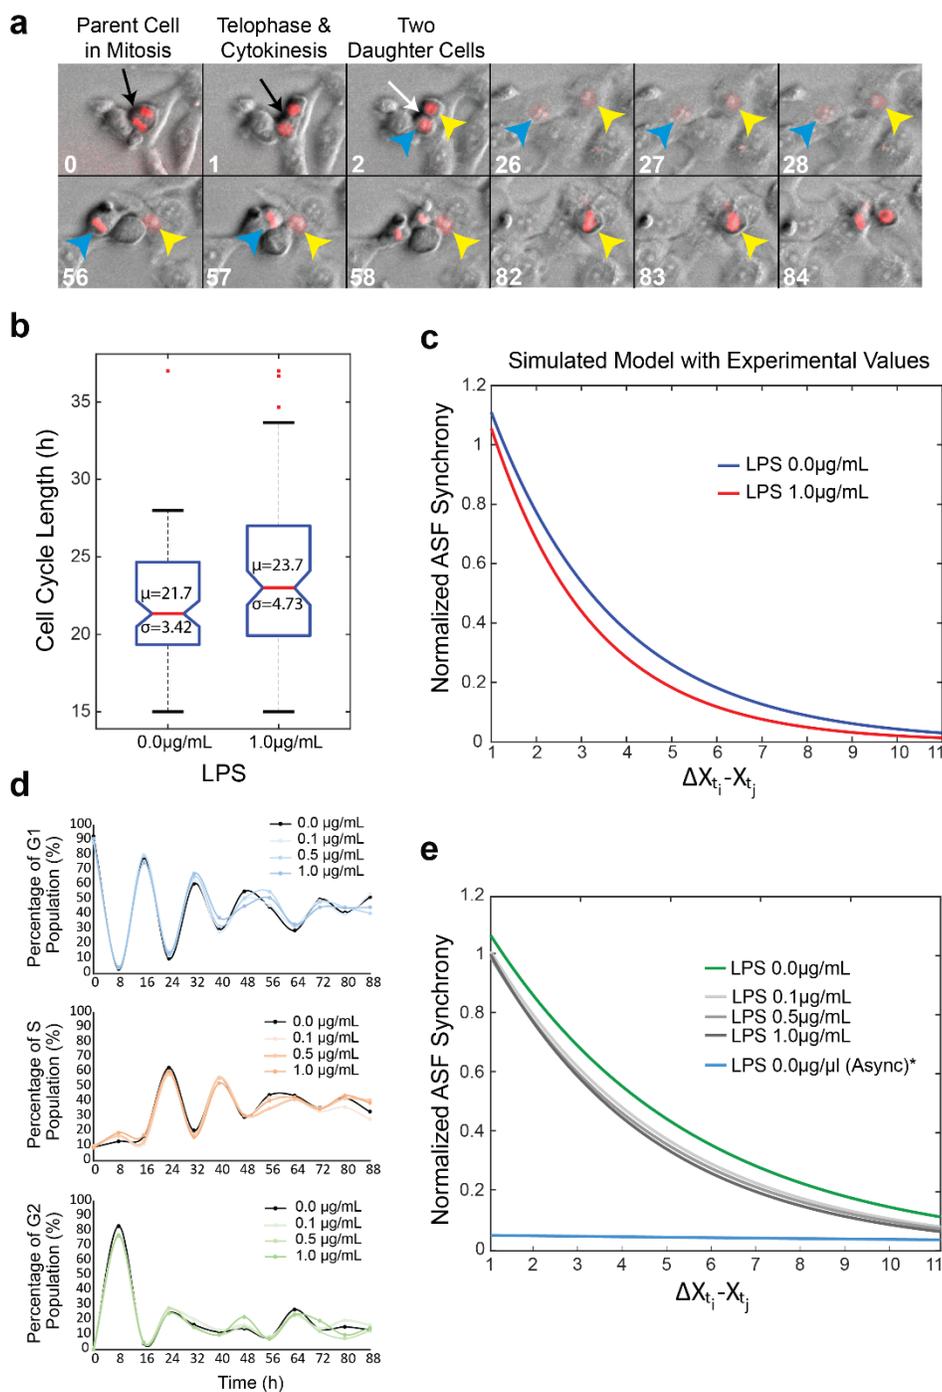

Figure 3.4: Noise variation of cell periodicity. a) Representative images of time lapse experiments. Once the septum (white arrow) is visible following cytokinesis, the cell cycle duration recording begins for both daughter cells (yellow and blue arrow). Both cells being cell cycle at Frame 2, and both daughter cells can be seen progressing through interphase in Frames 26-28. By the end of Frame 57, the first daughter cell completes the cell cycle and record

ends. The second daughter cell (yellow arrow) had a substantially longer cell cycle duration, which concluded at the end of Frame 84, thus demonstrating the inherent variability of cell cycle duration between identical cells within the population. b) Asynchronous cells were either treated with 1 $\mu\text{g}/\text{mL}$ of LPS or left untreated and cell cycle duration was recorded as described in Figure 4a. 100 cells were tracked for each condition and the population mean and standard deviation of cell cycle duration is shown. c) Values obtained from time lapse microscopy for cell cycle mean and standard deviation were used in our model to predict the impact on cell cycle desynchronization. The model revealed the LPS administration should result in an increased rate of cell cycle desynchronization d) Cell cycle phase distribution of various LPS concentrations following cell cycle synchronization for 88 hours post release. e) Normalized ASF scores for LPS-treated desynchronizing cells. The asynchronous population was not normalized in order to capture the overall linear trend.

3.6 Discussion

The cell cycle and subsequent daughter cell division is a central facet of cell biology from development and cellular differentiation to disease initiation and progression. While the process is tightly regulated and robust in a single cell, across a population we observe significant variability in period. Each cell within a given population contains measurable variations in their cellular content and housekeeping genes (e.g., differences in their RNA polymerases, ribosomes). These variations impact the expression of genes in what is known as extrinsic noise (Quarton et al. 2020; M. B. Elowitz et al. 2002; Kang et al. 2020; Raser and O'Shea 2004; Swain, Elowitz, and Siggia 2002). Furthermore, the cellular machinery responsible for progressing a cell through its cycle is intrinsically noisy as well. These intra and inter-cellular differences cause an initially synchronously in-phase population of cells to diverge as each progresses independently through their life cycle at varying rates (Chao et al. 2019).

Moreover, cell synchronicity is an essential aspect of mammalian biological homeostasis. The circadian rhythm is a molecular orchestrated process present in various tissues that synchronizes

biological outputs to the 24-hour day-night cycle (Patke, Young, and Axelrod 2019). It is composed of multiple master transcription factor regulators that are involved in robust feedback networks that enable these oscillatory functions in cells (Partch, Green, and Takahashi 2014). Importantly, cancer cells can become compromised with respect to these molecular actuators that enable cellular synchronization, and there is evidence that this disruption can enhance tumorigenesis (Sulli, Lam, and Panda 2019). For example, DNA repair mechanisms are tied to the circadian regulation (Sancar et al. 2010) and if these processes are disrupted it may lead to accumulating mutations and overall genome instability (Gery et al. 2006). Thus, understanding and modeling cell desynchronization at a single-cell level is a decisive approach to quantifying cellular changes that may impact oncogenesis (Barberis and Verbruggen 2017).

Here, using a combination of simulations and experiments we show that the variability in cell cycle period directly impacts the rate of desynchronization in a population of cells. The next line of investigation will include studying the factors that contribute to this variability at a single cell level, and the distribution between intrinsic and extrinsic sources of noise. Finally, a key direction of research is not just on how such a tightly regulated process can rely on stochastic variations, but also how diseased states such as cancer cells, utilize noise and if noise itself can become a contributor to disease progression. More specifically an intriguing hypothesis is that cancer cells obtain benefit by having higher noise in cell cycle periodicity, which yields ultra-slow and fast dividing cells. Moreover, this hypothesis opens the path for potential means to exploit variability in cell cycle period for therapeutic purposes.

SUPPLEMENTAL MATERIAL FOR CHAPTER 2

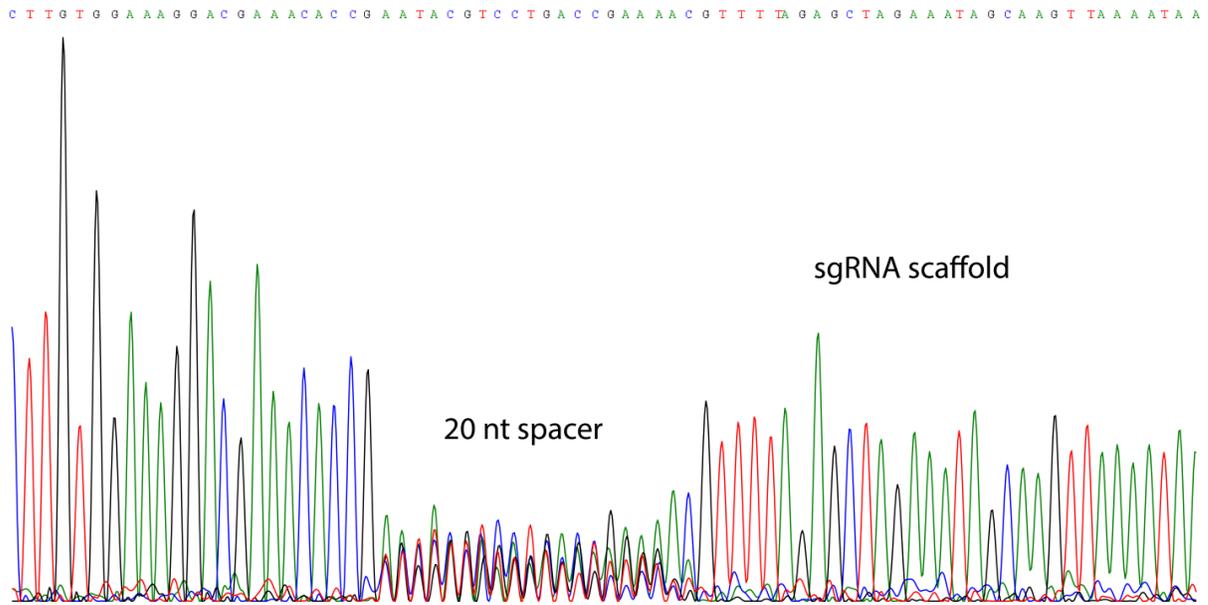

Figure A.1: Confirming the complexity of the CRISPR plasmid library. The CRISPR plasmid library was subjected to Sanger sequencing using primer P1, resulting in a 20-nt “noisy” target sequence closely matching the expected pattern from the 93 sgRNA oligonucleotide mixture.

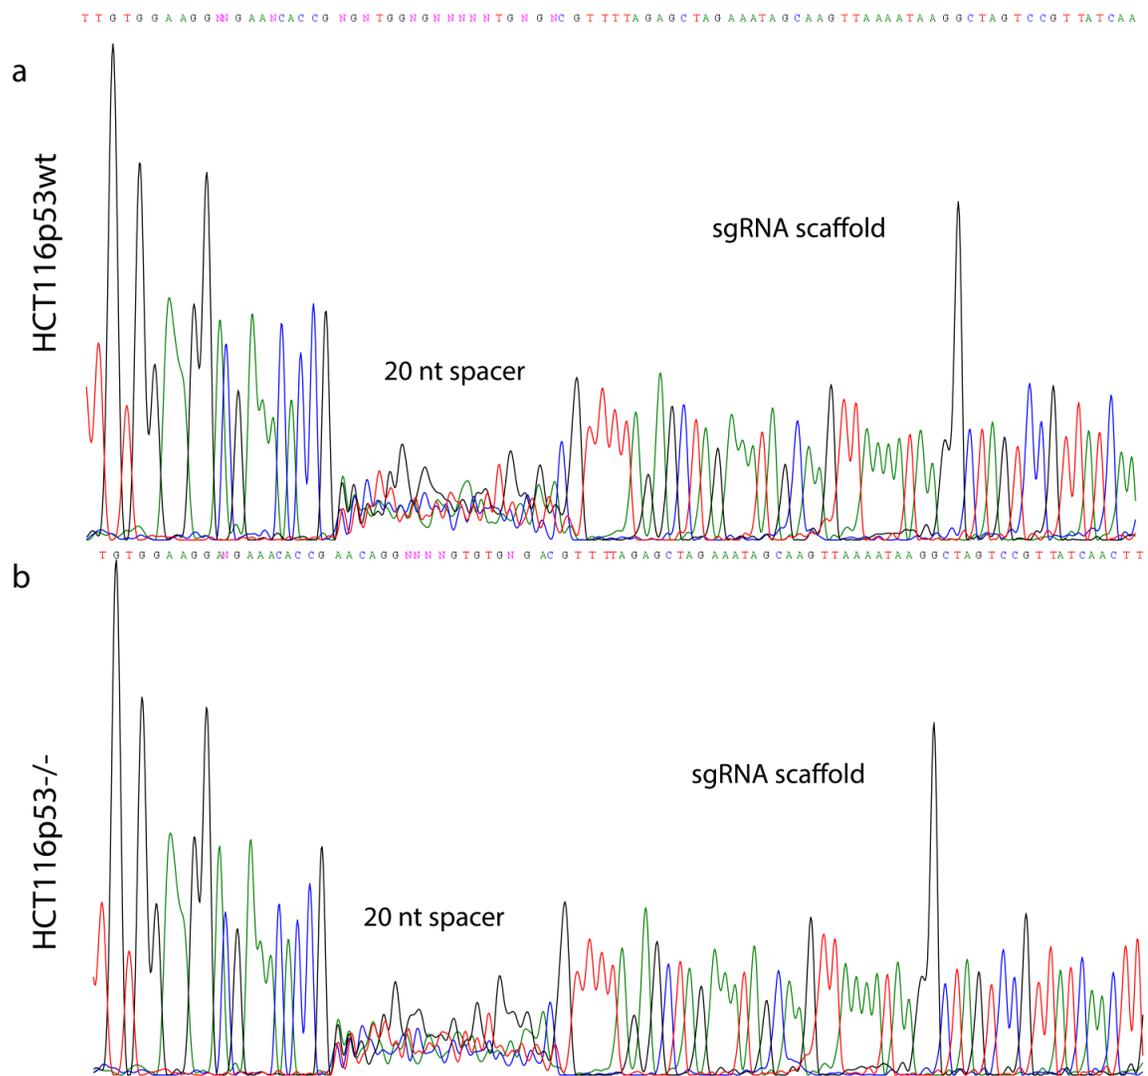

Figure A.2: Confirming the complexity of the CRISPR stable cell line libraries. The PCR fragments harboring the sgRNA constructs were amplified from the (a) WT-LIB and (b) KO-LIB cells by PCR and subjected to Sanger sequencing using primer P2, resulting in a 20-nt “noisy” sgRNA target sequence closely matching the expected pattern.

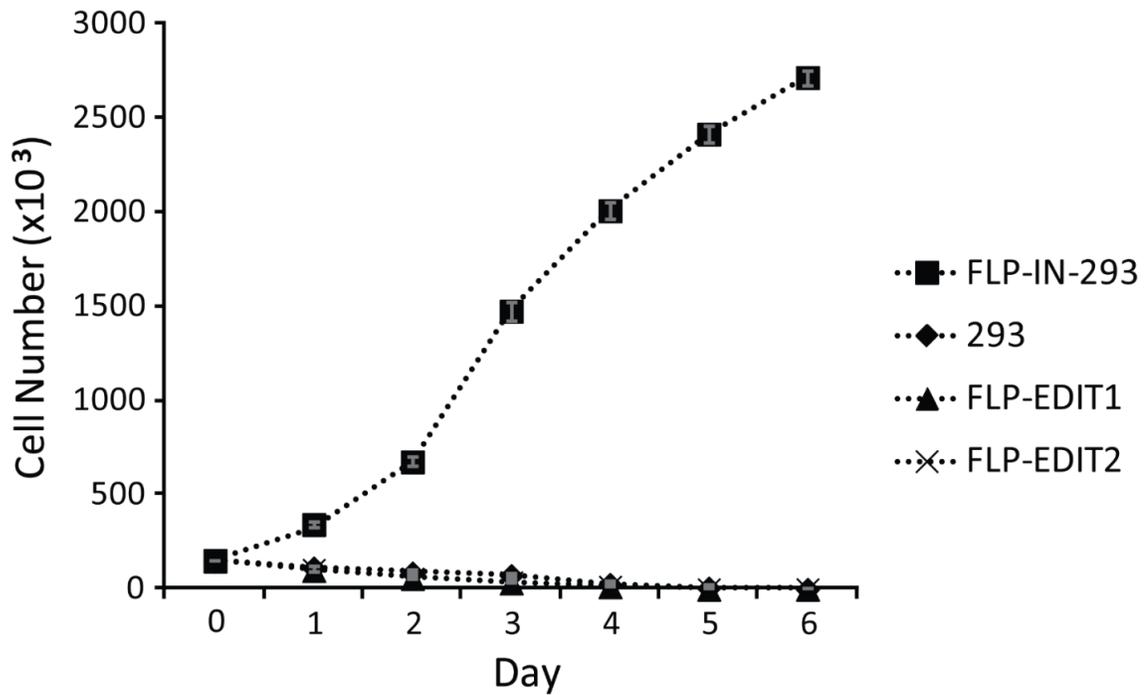

Figure A.3: Efficacy of the LentiCRISPRv2 system. Lentivirus was prepared targeting the open reading frame (ORF) of the zeocin resistance gene. On stable integration of these CRISPR constructs, the zeocin resistance cassette in the Flp-In-293 cells was effectively disrupted and the cells (FLP-EDIT1 and FLP-EDIT2) became sensitive to treatment with 100 $\mu\text{g}/\text{mL}$ zeocin.

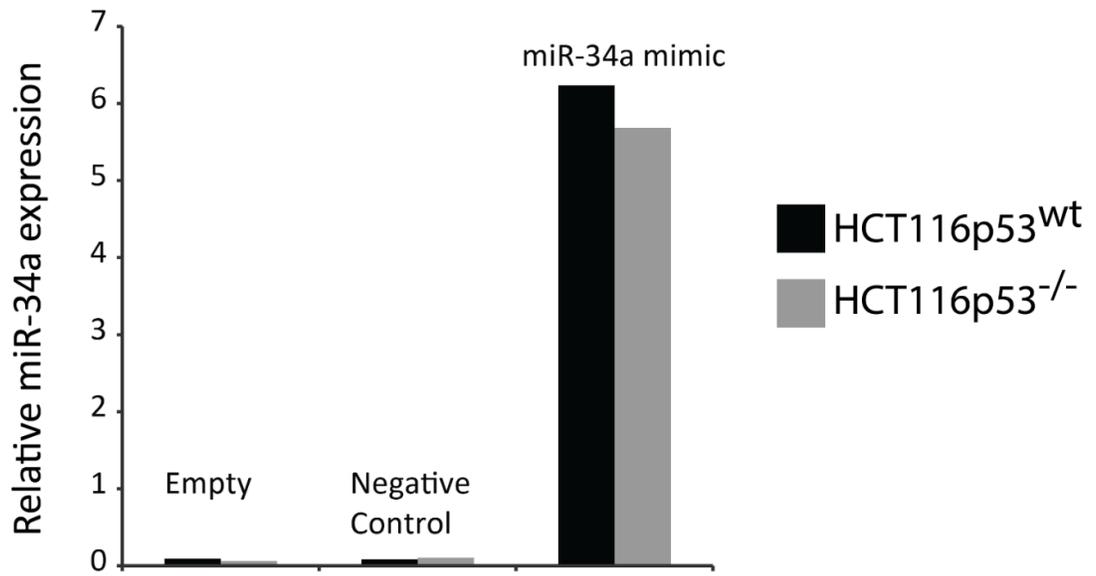

Figure A.4: Endogenous and ectopic miR-34a expression in HCT116p53 wild-type and p53^{-/-} cells. Empty represents cells that were not transfected with anything. Negative control represents cells that were transfected with 25nM of a miRNA mimic derived from *C. elegans* (cel-miR-67). miR-34a levels were measured relative to the small nuclear RNA U6.

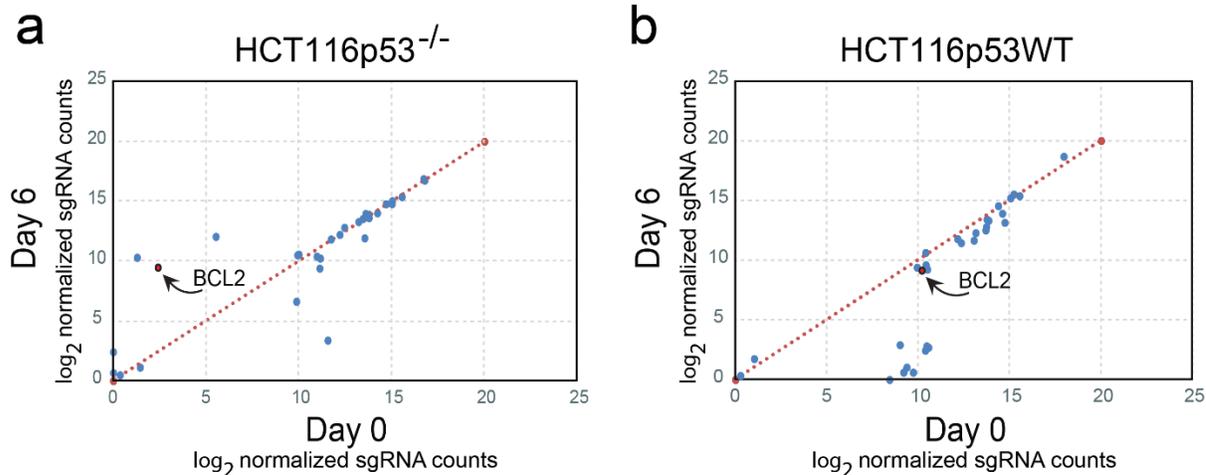

Figure A.5: High-throughput editing of edges with CRISPR libraries in (a) HCT116p53^{-/-} (LIB-p53^{-/-}) and (b) HCT116p53WT (LIB-WT) cells. 34 sgRNAs corresponding to direct miR-34a targets are shown. After 6 days treatment with 25nM of miR-34a mimic, LIB-p53^{-/-} cells showed an enrichment of the sgRNA targeting the miR-34a target site in the BCL2 3'UTR.

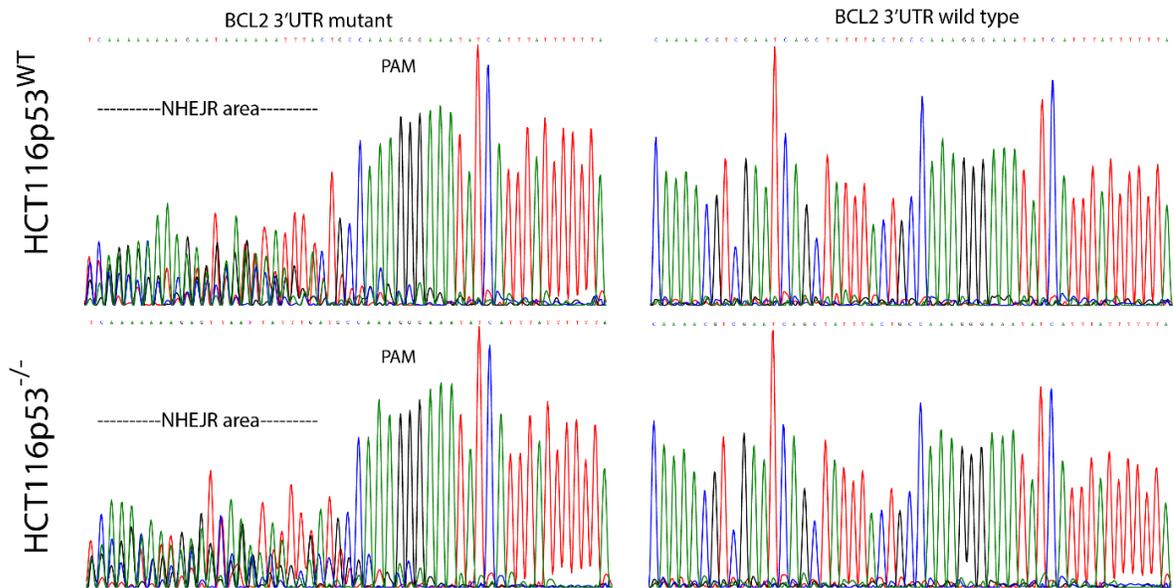

Figure A.6: Preparation of BCL2tgt-WT and BCL2tgt-p53^{-/-} stable cells. Sanger sequencing results for PCR products harboring the miR-34a target sites within the 3'UTR of BCL2 in BCL2tgt-WT (left, upper panel) and BCL2tgt-p53^{-/-} cells (left, lower panel) were included. Additionally, Sanger sequencing results for their corresponding parental cells (right, upper panel: HCT116p53^{WT}; right, lower panel: HCT116p53^{-/-}) at the same genomic location were included

Figure A.7: Alignment of wild-type and the most frequently detected indel sequences in BCL2tgt-WT and BCL2tgt-p53^{-/-} stable cells. NGS amplicon sequencing results for PCR products harboring the miR-34a target sites within the 3'UTR of BCL2 in BCL2tgt-WT and BCL2tgt-p53^{-/-} cells.

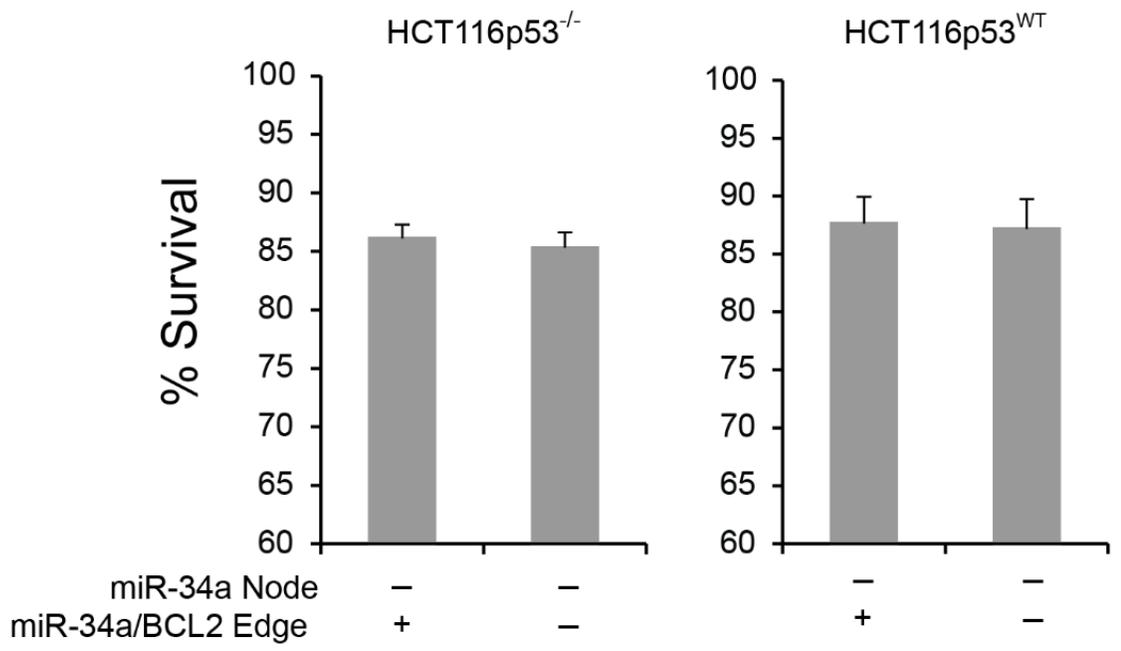

Figure A.8: Cell survival after miR-34a/BCL2 edge removal. In both WT and p53^{-/-} cells, the removal of miR-34a/BCL2 edge alone did not induce apoptosis.

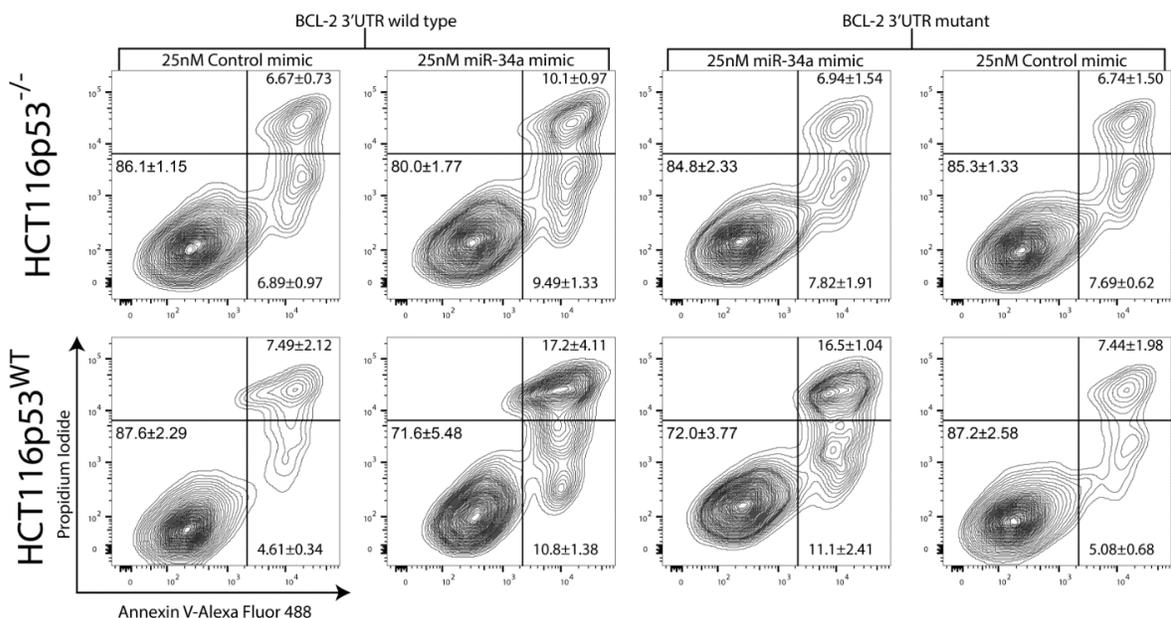

Figure A.9: miR-34a-induced apoptosis in WT, p53^{-/-}, BCL2tgt-WT and BCL2tgt-p53^{-/-} cells. As the cell initiates apoptosis it flips phosphatidylserine (PS) from the inner leaflet of the cell membrane to the outer leaflet. Annexin V binds externalized PS, giving a positive Alexa-Fluor 488 signal. As apoptosis progresses, the outer membrane loses its integrity such that the propidium iodide, which is typically impermeable to the cell, is able to enter the cell and bind nucleic acids giving a positive propidium iodide signal. Transfection of 25nM of miR-34a mimics induces apoptosis in the WT and p53^{-/-} cells. This effect is mitigated in BCL2tgt-p53^{-/-} cells, but not in BCL2tgt-WT cells

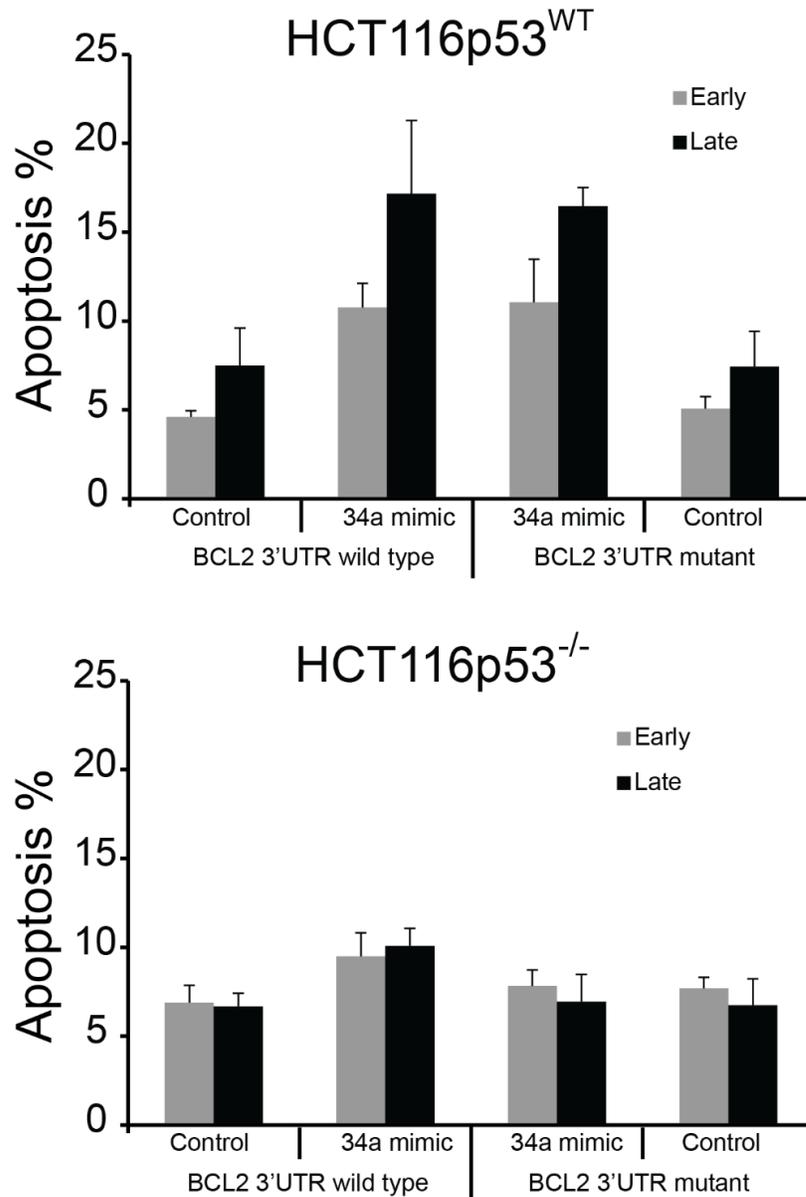

Figure A.10: Cells undergoing early and late apoptosis after miR-34a delivery. Ectopic miR-34a delivery induces early and late apoptosis in WT and p53^{-/-} cells. This effect is mostly abolished in BCL2tgt-p53^{-/-} cells, but not in BCL2tgt-WT cells, where the miR-34a target sites within the 3'UTR of BCL2 are disrupted.

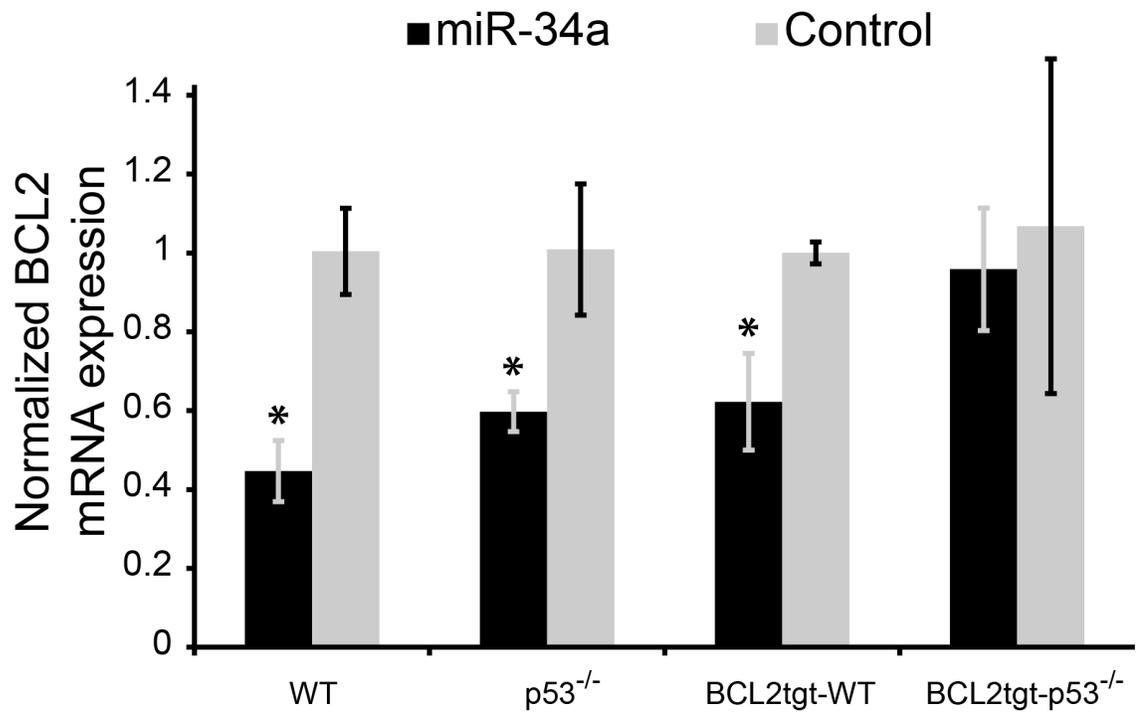

Figure A.11: Expression of BCL2 after miR-34a delivery. Treatment with miR-34a suppresses the expression of BCL2 in WT and p53^{-/-} cells. This effect is abolished in BCL2tgt-p53^{-/-} cells, but not in BCL2tgt-WT cells (* indicates p < 0.05).

APPENDIX B

SUPPLEMENTAL MATERIAL FOR CHAPTER 3

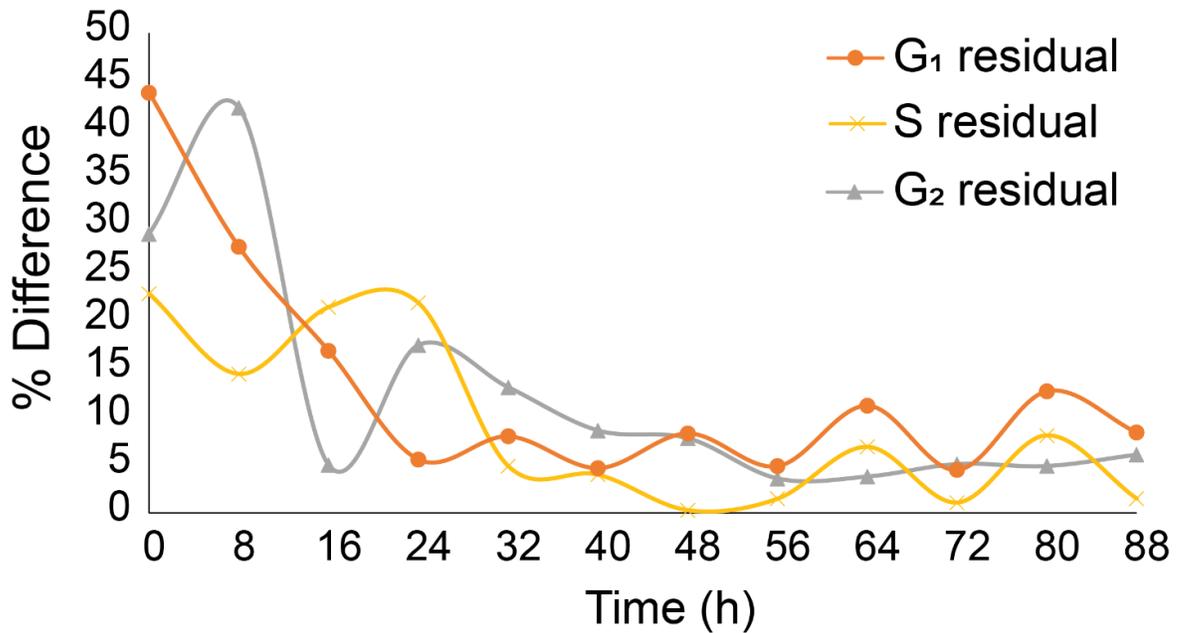

Figure B.1: Residual plot comparison of synchronous cells to asynchronous cells. The difference for each phase distribution for each time point demonstrates that overtime an initially synchronous population will converge to a static steady-state DNA distribution indicative of cells passing through the cell cycle asynchronously.

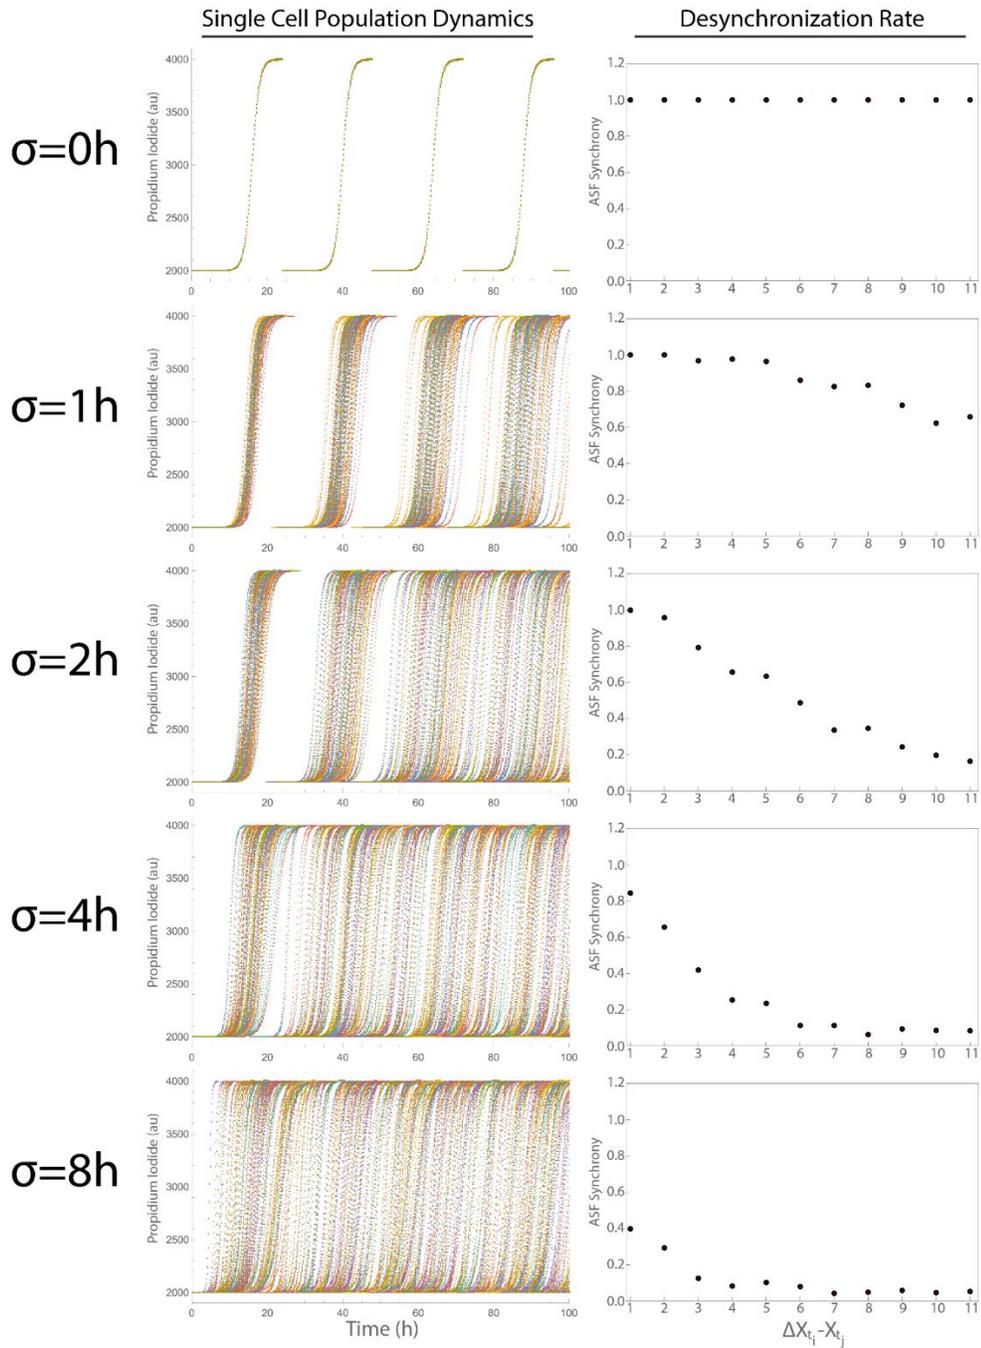

Figure B.2: Effect of population variance of cell cycle duration. If variance of the cell cycle is not incorporated into the model, not only does the model not recapitulate experimental observation, but the population of cells will never desynchronize. Therefore, we can assume that single-cell variance of the cell cycle is core component driving cell cycle desynchronization. Importantly, as variance is increased, the desynchronization rates increase. A standard deviation of 4 hours most accurately captures experimental observations. Furthermore, as the variance increases, desynchronization begins to approach an asynchronous trend.

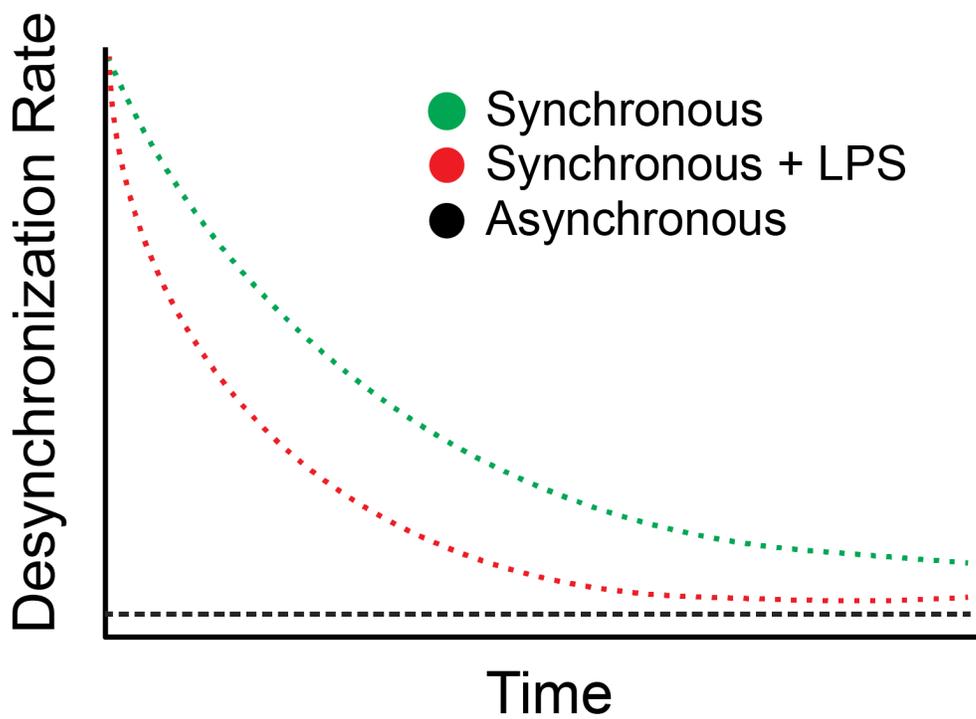

Figure B.3: Graphical hypothesis of LPS exposure to synchronous cell populations. If LPS exposure induces a greater degree of cell cycle variation starting from the same point of synchronicity, it would be expected that the desynchronization rates would increase, or rather reach an asynchronous trend sooner than cells not treated with LPS.

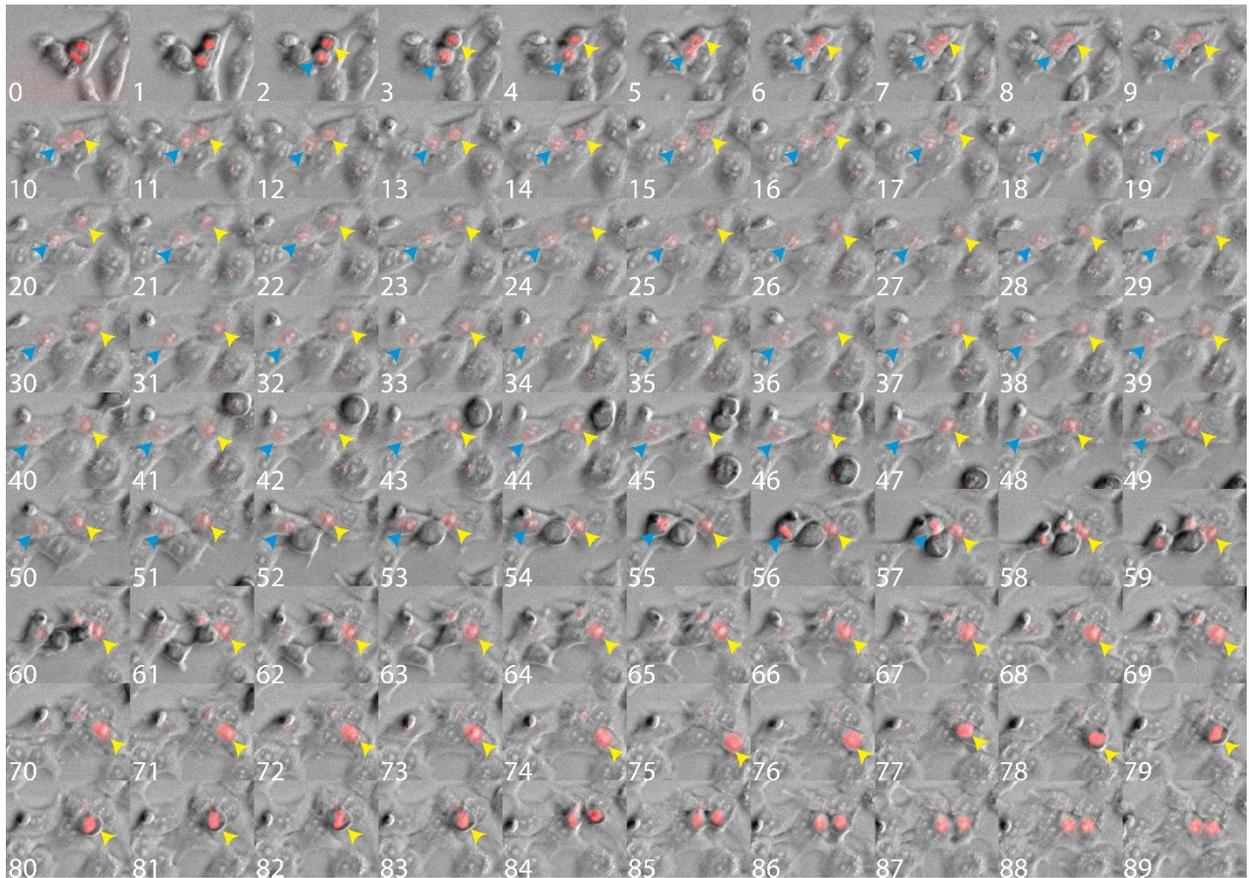

Figure B.4: Overall scheme of single-cell tracking of cell cycle duration. Timelapse microscopy of asynchronous cells performed for 72 hours at 20 minutes per frame. Frame 0 depicts a parent cell undergoing mitosis. Frame 1 show the parent cell undergoing telophase and cytokinesis. Once the septum is visible between the two daughter cells (yellow and blue arrow), the cell cycle duration begins being recorded. Frames 26-28 depicts cells progressing through interphase. At frame 56, one of the two daughter cells (blue arrow) begins metaphase, and by frame 58, the two resulting daughter cells are apparent and the cell cycle duration ends. Thus, the (blue arrow) daughter cell had a cell cycle duration of 18.3 hours (57 frames – 2 frames, multiplied by 20 minutes per frame). The other daughter cell (yellow arrow) had a substantially longer cell cycle duration of 27 hours, thus highlighting the inherent heterogeneity of cell cycle duration between identical cells within the population.

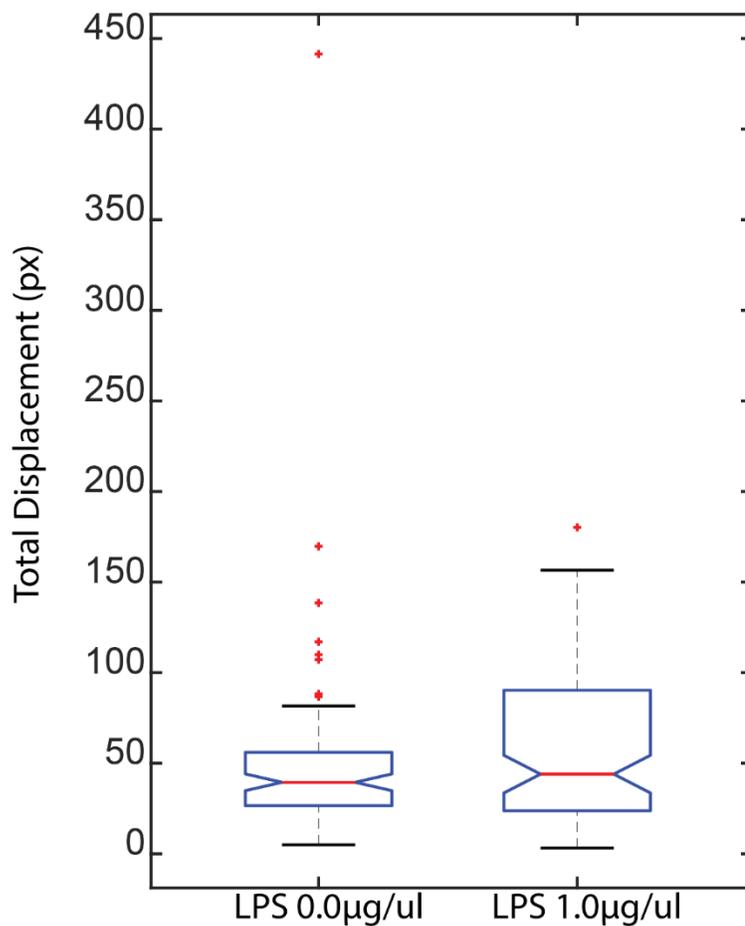

Figure B.5: Total displacement of single cells from time-lapse analysis. Cell coordinates were recorded both at the start and end of each cell that was recorded for single-cell cell cycle duration, and the total displacement was plotted for 100 cells for both conditions. LPS exposure had a large impact on the overall motility of cells. Total displacement was calculated with pixel coordinates using $d = \sqrt{(x_{start} - x_{end})^2 + (y_{start} - y_{end})^2}$.

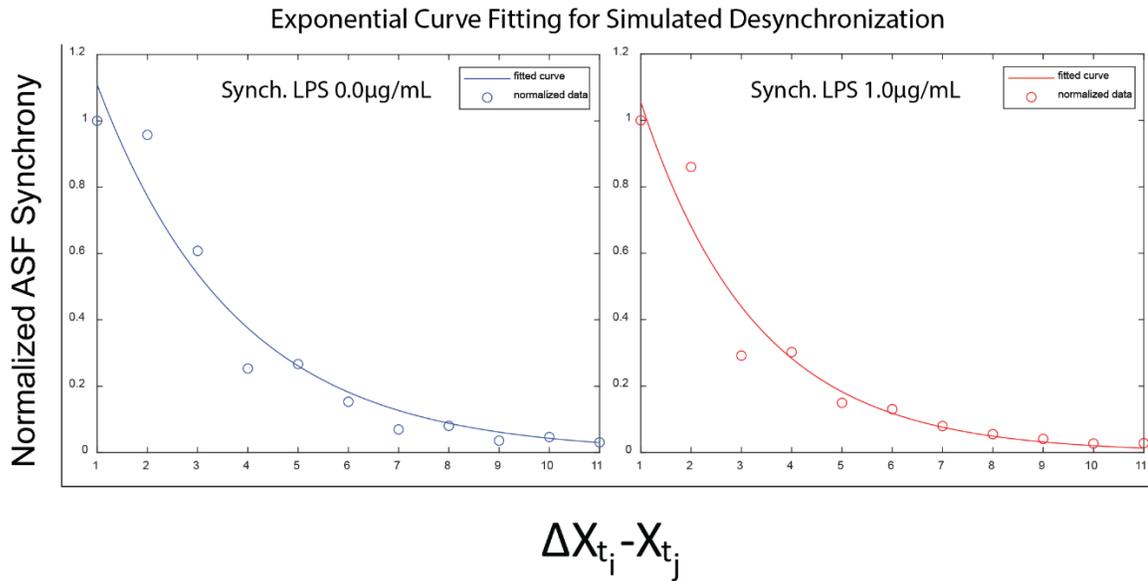

Figure B.6: Normalized and curve fitted desynchronization rates from simulated model using experimental values. The mean and standard deviation of the cell cycle duration obtained from single-cell time-lapse analysis were used in the simulated model to predict if the model was accurate in predicting resulting desynchronization rate. All ASF scores were normalized to the first value ($X_{t_0} - X_{t_8}$) in order to compare synchronous population trends to asynchrony. The normalized data points were fit with exponential curves.

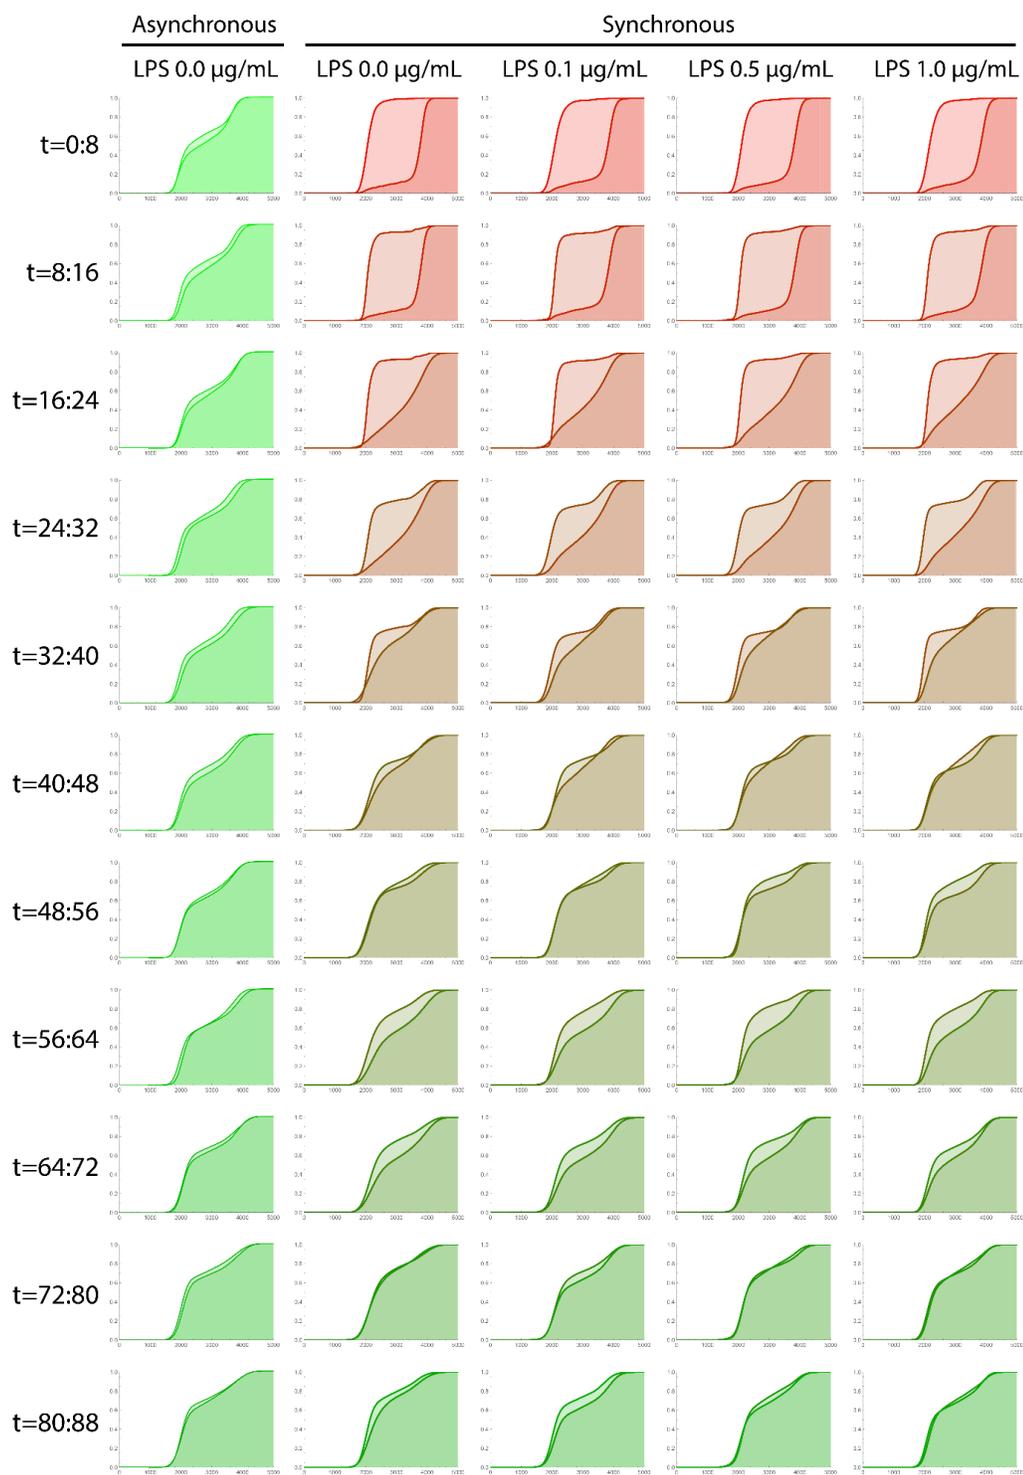

Figure B.7: ASF methodology for cell cycle desynchronization for LPS treated cells. Pairwise comparison of cumulative distribution function for propidium iodide-stained cells for each condition tested.

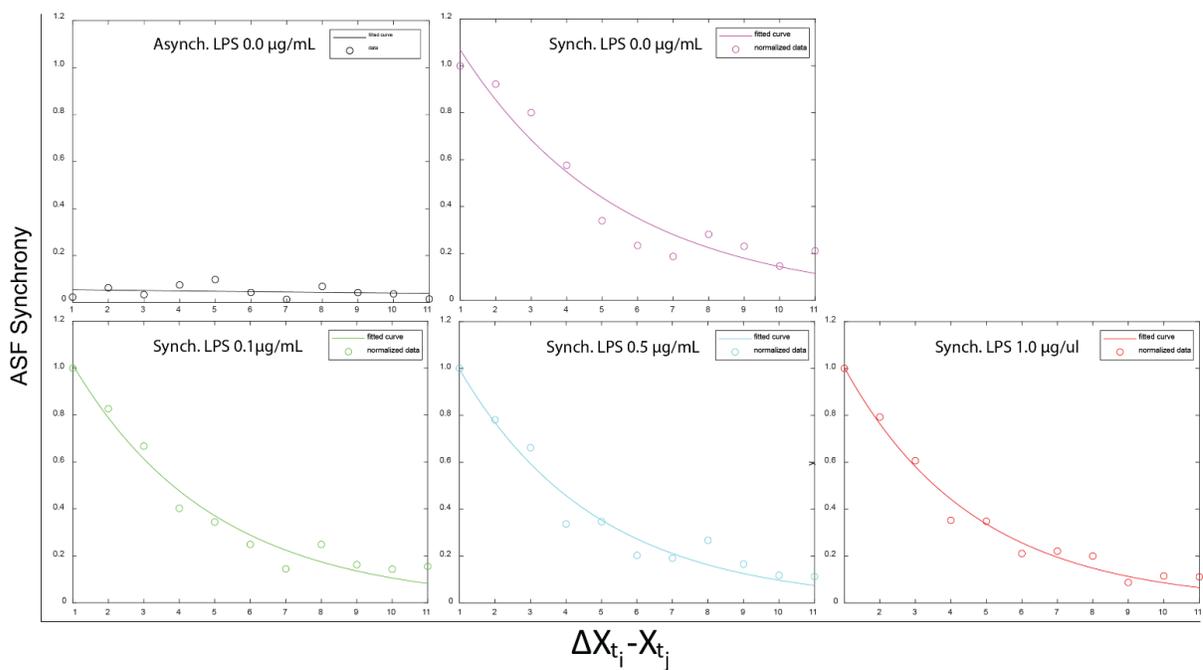

Figure B.8: Normalized and curved fitted desynchronization rates for synchronized cells. All ASF scores for synchronized cell populations treated with varying concentrations of LPS were normalized to the first value ($\mathbf{X}_{t_0} - \mathbf{X}_{t_8}$) in order to compare synchronous population trends to asynchrony. The normalized data points were fit with exponential curves. Asynchronous population was not normalized to retain linear trend.

BIOGRAPHICAL SKETCH

Chance Michael Nowak was born in Lafayette, Louisiana on March 20th, 1991. He graduated from Lafayette High School in 2009. He went on to receive his Bachelor of Science degree in Biological Sciences as well two minor degrees in Chemistry and Philosophy from Louisiana State University in 2013. In 2014 he worked as a Research Associate I at Louisiana State University before enrolling in the Molecular and Cell Biology Graduate Program the same year. He received his Master of Science degree in 2016. He then continued his doctoral research in systems and synthetic biology.

CURRICULUM VITAE

Personal Statement:

I am a hardworking and highly motivated doctoral student that has acquired an extensive depth of knowledge in the field of mammalian systems and synthetic biology through both wet lab work and in silico analysis that center on genome editing, gene delivery, and genetic circuit designs. Furthermore, I have strong track record of collaborations in many areas of scientific inquiry working alongside many scientists from diverse backgrounds for project completions, which often necessitated strong communication skills between individuals of disparate disciplines. I am seeking a scientist position in the biotechnology industry where I can utilize these skills for team management and project completions. My career goal is to assume a role that allows me to direct scientific research and execute team leadership in cutting-edge technologies for the purpose of developing genetic-based therapies that transforms patients' lives.

Education:

Bachelor of Science, Biological Sciences; Minor(s): Chemistry and Philosophy
December 2013, Louisiana State University, Baton Rouge, LA

Master of Science, Molecular and Cell Biology
September 2014-May 2016, University of Texas at Dallas

Doctor of Philosophy, Molecular and Cell Biology
June 2016-Present, University of Texas at Dallas
Expected graduation December 2021

Research Experience:

Undergraduate Research
Jan. 2013-Dec. 2013, Biological Sciences Department, Louisiana State University
Investigation of alternative functions of RNA Polymerase III in *S. cerevisiae*.

Research Associate I
Jan. 2014-Aug. 2014, Biological Sciences Department, Louisiana State University
Investigation of global defective RNA polymerase III complex assembly in *S. cerevisiae* and effects on the Pol II transcriptome.

Masters of Science
September 2014-May 2016, University of Texas at Dallas
Investigations into genome editing of cancer-relevant transcriptional regulatory motifs including microRNA binding sites and transcription factor binding sites.

Doctor of Philosophy, University of Texas at Dallas

Investigations into cell cycle control through mathematical modeling of DNA kinetics over time from synchronized cell populations as well genome editing of cell cycle control genes such as CDK4.

Research Interests:

Systems and Synthetic Biology
Biotechnology Research and Development
Genome Editing and Cell Engineering
CAR-T therapy
Transcriptional Gene Control
Epigenetic Gene Regulation
Chromosome Architecture and Chromatin Remodeling

Experimental Skills:

Flow Cytometry
Mammalian Cell Culture (HEK293T, HCT116, HeLa, MCF7, PBMC, etc.)
Viral production in mammalian cells
Genome editing (extensive knowledge of CRISPR-based systems, including base and prime editors)
NGS analysis (genome editing)
RNAseq analysis
Molecular cloning
Site-specific mutagenesis of plasmids and yeast
Yeast tetrad dissections
Analysis of mutant recombinants
DNA, RNA, and protein extractions
Northern and Western Blotting
cDNA synthesis and 5'RACE
Oligonucleotide design
Radiation safety certified

Presentations:

2nd International Conference on CRISPR Technologies, presented by **Chance M. Nowak**

“CRISPR-Based Editing Reveals Edge-Specific Effects in Biological Networks”
Yi Li, **Chance Nowak**, Daniel Withers Alexander Pertsemlidis, and Leonidas Bleris

Posters:

2016 Third International Mammalian Synthetic Biology Workshop, presented by **Chance M. Nowak**

“Exploiting the CRISPR/Cas9 PAM constraint for single-nucleotide resolution interventions” Li, Y., Mendiratta, S., Ehrhardt, K., Kashyap, N., White, M. A. and L. Bleris

2018 Fifth International Mammalian Synthetic Biology Workshop, presented by **Chance M. Nowak**

“CRISPR-Based Editing Reveals Edge-Specific Effects in Biological Networks”
Yi Li, **Chance Nowak**, Daniel Withers Alexander Pertsemlidis, and Leonidas Bleris

2018 AIChE Annual Meeting, presented by **Chance M. Nowak**

“CRISPR-Based Editing Reveals Edge-Specific Effects in Biological Networks”
Yi Li, **Chance Nowak**, Daniel Withers Alexander Pertsemlidis, and Leonidas Bleris
